MEDINFO 2010

Studies in Health Technology and Informatics

This book series was started in 1990 to promote research conducted under the auspices of the EC programmes' Advanced Informatics in Medicine (AIM) and Biomedical and Health Research (BHR) bioengineering branch. A driving aspect of international health informatics is that telecommunication technology, rehabilitative technology, intelligent home technology and many other components are moving together and form one integrated world of information and communication media. The complete series has been accepted in Medline. Volumes from 2005 onwards are available online.

Editorial

The 13th World Congress on Medical and Health Informatics, Medinfo 2010, held in Cape Town, South Africa has many forms of participation from preconference tutorials, workshops, keynotes, invited presentations, scientific presentations, panels, demonstrations, and posters. The Organizing Committee, led by Dr. Lyn Hanmer from South Africa, collaborated with the Scientific Program Committee, led by Drs. Riccardo Bellazzi from Italy and Johanna Westbrook from Australia, to sculpt an outstanding program. The Editorial Committee has tried to organize a subset of this rich content, the scientific papers and abstracts of posters, into the Proceedings.

Our greatest challenge has been to make each paper have identical formatting. Only 10% of all submitted papers exactly complied with the organizers instructions. Further work break down analysis shows total editorial time (excluding meetings) of approximately 200 hours, evenly spread between posters and papers. Of that 200 hours, two-thirds are corrections in to conference requirements, and one-third is formatting in to publisher's requirements. We thank Christine Archuleta for her diligent copy editing.

We have organized the paper Proceedings into 20 chapters, where the last chapter is comprised of the abstract of posters organized by the authors self-selected theme. We have attempted to organize the scientific papers in 19 chapters starting with the individual and moving through an ever expanding view of organization and systems.

Of course, most papers could easily have fit into multiple sections, so we not only provide a keyword index, but also a searchable CD-ROM version.

Preface from the Scientific Program Co-Chairs

The theme for the International Medical Informatics Association's (IMIA) 13th World Congress on Medical and Health Informatics, Medinfo 2010 is Partnerships for effective e-Health solutions. It is well recognised that information and communication technologies have enormous potential for improving the health and lives of individuals. Innovative and effective change using such technologies is reliant upon people working together in partnerships to create innovative and effective solutions to problems with particular regard to contextual and environmental factors.

Medinfo 2010 brings together the health informatics community from across the globe with a focus on how we can work together and share our experiences and knowledge to promote sustainable solutions to the challenges presenting to us all. This will be an historical event as Medinfo 2010 is hosted in Africa for the first time.

The Scientific Program Committee (SPC) was presented with a strong field of 905 submissions meeting the call of the congress challenge. This included 603 papers, 203 posters, 41 workshops/tutorials, 37 panels and 21 scientific demonstration applications. The final paper acceptance rate was 43%. All papers were assigned to two or three reviewers who scored each of the papers and provided feedback to authors. All submissions were categorised into one of four major themes (Hospital information systems, Consumer-health informatics, Knowledge management, National and International Health IT) and submissions within each of these theme areas were re-reviewed by assigned members of the SPC.

The final program covers all aspects of modern health informatics, ranging from traditional topics, such as hospital information systems, patient registries, nursing informatics, data integration, standards, interoperability issues and decision support, to new topics such as translational bioinformatics, text mining, intelligent data analysis, emerging technologies, quality, social networking, workflow and organizational issues. The papers have been selected with the guiding principle of including in the program both high quality methodological research and high impact applications of health informatics. In some cases, the authors achieved both goals.

A distinguishing feature of Medinfo 2010 program is the presence of several sessions on public health and national and international initiatives to promote health IT. The scientific challenges to implement large-scale initiatives are strongly related to the conference theme, as they rely on effective partnerships between all actors involved in health care informatics. The scientific rigor of the congress papers can be seen both as a consequence and reflection of IMIA's strategic decision to see its role as a promoter of science and health IT throughout the world. Health Informatics researchers internationally are rising to the challenge of providing robust evidence of the transformational effects of effective health information exchange.

The Scientific Program Committee thanks all those who made submissions to Medinfo. Special thanks also go to the worldwide team who reviewed these submissions and provided feedback. For the first time the SPC organised a mentor scheme which provided the opportunity for researchers seeking to

submit papers to Medinfo to have their work reviewed by an international expert prior to the Congress submission closing date. 42 papers were reviewed as part of this process. We thank the team of mentors who generously gave their time to support their colleagues as part of this scheme.

Message from the IMIA President

Medinfo 2010 is the 13th World Congress on Medical Informatics and the first held in Africa! The Convention Center in Cape Town, South Africa is an outstanding conference site with excellent facilities to hold the premier triennial international meeting for the medical informatics community. The conference theme selected for Medinfo 2010 is a topic that most countries are currently addressing: Partnerships for effective eHealth solutions – Innovative collaborations promote solutions to health challenges.

A Medinfo conference brings together world leaders in this field to share knowledge and experiences. Medinfo 2010 is a unique opportunity to meet these leaders and to hear of, and contribute to, advances in biomedical and health informatics. There is nothing else like a Medinfo conference.

A Medinfo conference is the official conference of the International Medical Informatics Association (IMIA). IMIA's goals and objectives include:

- the promotion of informatics in health care and biomedical research,
- the advancement of international cooperation,
- the stimulation of research, development and education, and
- the dissemination and exchange of information.

For more than 40 years, IMIA has been a bridging organisation, as medical informatics is an integrative discipline. IMIA supports and stimulates high-quality translational communication, research, education, and practice in biomedical and health informatics. In IMIA's Medinfo conferences this is done by bringing together, from a global perspective, scientists, researchers, informatics practitioners, vendors, consultants and suppliers in an environment of cooperation and sharing. This Medinfo includes a special focus on the needs of and solutions from developing countries, in Africa and beyond.

These conference proceedings will help to share the knowledge, presented and discussed at this Medinfo. As for the previous Medinfo conferences, the proceedings contain important results in research and education, and also for the practise of health care.

Medinfo 2010 has been organised and coordinated by the South African Health Informatics Association. A number of governmental organisations, associations and businesses have agreed to be sponsors. Many persons have worked hard and successful for making Medinfo 2010 a great success. Let me here in particular acknowledge the chairpersons of the Organising Committee, Lyn Hanmer (South Africa); of the Scientific Program Committee, Riccardo Bellazzi (Italy) and Johanna Westbrook (Australia); and of the Editorial Committee, Charles Safran (USA).

The Role of Patients in Transiting Personal Health Information: A Field Study

Yunan Chen

College of Information and Computer Science, University of California, Irvine

Abstract

Recent consumer health informatics initiatives advocate individual access and management of personal medical records. However, little is known regarding the impact of personal access of health information on clinical practice. This paper introduces a field study investigating the usage patterns of personal health records in medical consultations. The self-managed records provide patients with a strong sense of ownership and control over their own health information. Personal medical records have been used primarily for transiting information among different providers. This behavior changed patient-provider communication into a records sharing. Doing so effectively eliminated the potential errors in the verbal reporting process. This study indicates that patients can be effective contributors to their own health and suggest the design of health information systems to rethink the role of patients in the healthcare process and shift the responsibility of healthcare to the patients' side.

Keywords:

Medical records, Physician-patient relations, Cooperative behavior, Access to information, Consumer health information, Information management

Introduction

Recent consumer health informatics initiatives encourage individual access and management of medical records using Personal Health Record (PHR) system. PHR has been previously defined as personal notes documenting important medical information such as medical history and current medications [2, 3]. A large-scale survey [1] shows that approximately 40% of people maintain some form of paper medical records, while only 1.5% use computer tools to manage their health information.

Online PHR is therefore "*an electronic application through which individuals can access, manage, and share their health information and that of others for whom they are authorized, in a private, secure and confidential environment* [4]." PHR is believed to be able to improve patient-provider communication and empower patients to engage into their own health [5-7].

While the focus of current PHR study is usually on the patients' side, accessing and managing personal health information also affects the way in which medical consultation is conducted. The information contained in patients' records is crucial for physicians to make correct medical decisions and to apply optimal care. This information, however, is often managed by individual healthcare organizations where a patient previously sought care. It is notable that to date, there is little information as to how personal managed health records manage in actual clinical practice [4].

This paper describes an observational field study that was conducted in urban China, a place where patients are responsible for maintaining their outpatient medical records. We shadowed doctor-patients interactions in consulting rooms in order to understand the usage patterns of paper-based PHR in the medical consultation process. Our observations suggest that for patients, their medical records are transitional artifacts that carry critical information among the multiple physicians they visit. Using personal health records has turned the question-answering mode of clinical interviews into an information-sharing practice. This ensures the accurate medical history is communicated to the providers. It also fosters an effective collaboration between patient and provider where part of the responsibility is shifted to the patients' side. Maintaining their own health records provides a sense of control among patients and encourages them to be more involved in their own health. These findings can be used to direct future PHR system design and to impact chronic disease management.

Methods

This observational study was conducted in an outpatient department of a large hospital located in urban China. The primary reason this field site was chosen is that outpatient (ambulatory) medical records are routinely kept by individual patients in current Chinese medical practice. We obtained IRB approval from the university the researcher is affiliated with, and the approval of the scientific review board of the hospital being studied. All the participants' names are pseudonyms in order to protect their confidentialities.

Participants

The hospital where this study was carried out is well known for its medical expertise in the fields of ophthalmology (eye) and otorhinolaryngology (ENT). Most patients in these two departments are non-locals looking for second opinions or hoping to be treated for diseases that are untreatable elsewhere. By contrast, the other departments consist mainly of local patients. The whole hospital is under resourced due to the large demand of patients care. To observe the medical records usage patterns in both the departments of expertise and non-expertise, we recruited four doctors from the outpatient departments, including two internal medicine physicians, one eye doctor and one ENT doctor. A total of seventy-six patient consultations were observed during the study.

Data Collection and Analysis

The field observations were intended to identify usage patterns of patients' self-maintained medical records during the consultation process. A total of 40 hours of observations were performed in the consulting room. Each observation session lasted for 4-5 hours. Usually, the researcher sat in an unobtrusive location within the consulting room (Figure 1). The research activities included jotting down brief observation notes, asking questions when patients/physicians were available, and tracking down critical incidents during the observations. Detailed observation notes were transcribed after each session. The researcher is a native Mandarin speaker and previously majored in medicine. This ensured proper understandings of the patient-physician interactions in the consulting room. Overall, over 120 observation notes were summarized.

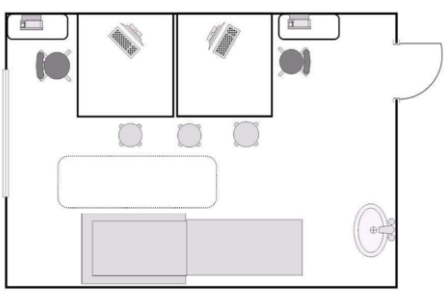

Figure 1- The physical layout of the medical consultation room. The physician sits on the left side at a desk. Student 1 was at the right side desk entering information into the HIS system. The three horizontal chairs were for: patient, student 2, and the observer (from left to right).

The observation notes were coded using an iterative open coding scheme [8] to extract the medical records usage patterns in the consulting room. These findings were verified with participating doctors and other clinicians in the hospital.

Results

In this section, we report medical records usage patterns in the consulting room sequentially following the general clinical workflow in the following three steps: sharing records, checking records and making decisions.

Sharing Records

Keeping one's own outpatient medical records are a predominant phenomenon in Chinese medical practice where patients receive their own records in almost every healthcare organization. Similarly, patients in the current study have full access to their medical records. ***Full access*** means that patients are able to maintain all their medical information generated in healthcare settings, including diagnoses, prescriptions, clinical notes, lab results, and even hardcopies of radiology images. The hospital in urban China is equipped with a Hospital Information System (HIS) where doctors can enter medical orders and diagnoses directly to the HIS system. To ensure that patients have full copies of their medical information, the information typed in the HIS system is always printed out and attached to a medical records book that is used to document their other health information. The records book is used in all healthcare organizations in the region. Patients then keep the records book at home as their own personal health information.

Figure 2- In the Eye consulting room, a family member holding a CT image the patient received from his local hospital – thousands miles away from the study site.

These self-maintained medical records are brought back to the consulting rooms by patients later on. Carrying medical records is a way for patients to share past medical history with current doctors. During observations, patients often came in with a stack of medical record books that they had collected from different healthcare providers or from different time spans, such as from the earliest disease onset to the most recent treatment. In our study, 74 out of 76 patients brought in their own personal medical records.

Xiaoxia is local patient with 20 years of diabetes treatment who also suffers from multiple complications of her illness. She told us why she carries her medical records with her at all times:

> "*I need to go to hospitals frequently. Sometimes when I felt uncomfortable or when I suddenly have a couple of hours free time during work, I just go*

to see a doctor. This small book is easy to carry and I always put it in my purse. That way I don't need to go back home to pick up my records and I can go whenever I want to!"

Later on in the consultation, she took out a couple of medical record books that she recently received from other doctors, including a cardiologist, physician from the community hospital and a Chinese medicine doctor to show her physician. In Xiaoxia's opinion, having medical records is a requisite to seeing her doctors and carrying her records is a convenience that allows her to stay healthy.

Checking Records

Patients have to turn in their most recent medical records to the receptionist with their registration numbers before entering the consulting room. They are allowed to keep with them other medical records, *e.g.* medical records from the past year or smaller pieces of information patients prepared at home, *e.g.* glucose readings in the past two weeks. The medical records the receptionist takes are then put on the physician's desk for review. The physician's work starts with the placement of the records book on the desk. For the first few minutes of the consultation, the patient just sits quietly and waits for their doctor to review their records.

The review process of the medical records starts from the most recent medical visit, then traces back to earlier visits until doctors get an overview of the patients' situation. In the cases of the Eye and ENT departments, where most patients present with relatively severe diseases, the assistant often requests patients hand in all their past medical records along with original radiology images. The Eye/ENT doctors then carefully examined this information and observe the images before the patient begin reporting their symptoms.

After reviewing the recent records, patients start communicating with their doctors verbally about their feeling and symptoms as well as past medical history and history of present illnesses. The interview process generally consists of a series of questions and answers so that doctors can obtain sufficient information to make their judgments. Hence, the ability to effectively communicate personal health information is closely associated with the quality of personal healthcare. Previous studies [9, 10] show that patient-provider communication may be hindered by the ineffective information reported by patients, especially those who have low health literacy. Similar observations happened in our study where patients frequently faltered and had difficulty answering questions, even when the questions were regarding their own experiences. Many of these moments of communication breakdowns were followed by a medical records sharing session where patients took out written documents that helped facilitate the expression of their thoughts. These documents were mostly the medical records that were not turned in at the beginning of the consultation. Xiaoyi is a local patient who came in to see Dr. Yang. During the consultation, Dr. Yang routinely asked what medications and lab tests she had recently. Xiaoyi pondered for a while and started complaining:

"*These pill names are* just *too hard to remember, I think I will never remember them. You know, I have diabetes, hypertension and heart diseases. I need to take more than 10 types of medications everyday. I am 74 years old and I don't have lots of medical knowledge. How could possibly that I can remember these names myself"*

However, after a few seconds of thinking, Xiaoyi took out a small medical records book in which her past medical visits had been documented. She passed this record to Dr. Yang and pointed to a few prescriptions she is now taking. Sharing medical records allows Xiaoyi to report her medical information to the doctors quickly without taking too much effort to remember it. This sharing process is especially beneficial for older patients who might have memory loss and limited medical knowledge. It also saves valuable consulting time in such an under resourced healthcare setting.

Making Decisions

Not only do physicians look to past diagnoses and prescriptions to substitute some oral communication, they also check other information such as radiology images or laboratory tests when it is available to them. To physicians, this information demonstrates a disease's progress from earlier onset to the various treatments already used. It also helps physicians to eliminate their initial hypothesis about an illness. And as physicians almost inevitably request lab and radiology images from patients when reading their basic medical records, medical records help to exclude previously tried medical procedures.

A young man came in with his mother to see Dr. Jiang – a well-known eye specialist. The young man reported a recent loss of vision on his left eye. The loss was getting worse and they suspected that it might be related to an injury that happened seven years ago. Dr. Jiang's first inquiry was about the seven year old injury. The mother took out the records they had received 7 years ago from her purse. Even though the paper records were a bit torn, Dr. Jiang could still get a pretty good sense of what the medical condition was when the injury happened.

After viewing the records, Dr. Jiang did a simple ophthalmoscope check and told the patient:

"Ok, I think you should only take a retinal photograph. You should be able to get results this afternoon. Your precious radiology images seem clear that the lost vision has nothing to do with your injury. You know, it could have cost you weeks to get CT tests here."

Here the personally maintained medical records changed the medical decision making process. Medical decision-making is essentially a hypothetical-deductive process. With more clinical evidence available at the point of care, physicians can eliminate unrelated hypotheses during the initial medical decision-making process. Narrowing down initial hypotheses saves patients from doing unnecessary tests and shortens the overall

diagnosis time. As shown in our observation, for the patients who travel to consult second opinions in the Eye or ENT departments, medical records may save weeks from the waiting time.

Discussion

In this study, we found that personal health records have been used as a means to transmit an individual's professional health information among their various healthcare providers. These medical records are brought to a consulting room and shared with the physician during the consulting process. Patients then add the newly received records to their personal health information repositories. In this section, we discuss the implications of this medical records usage patterns to clinical practice.

Patient-centric Record Keeping

Fragmentation is a term that has often been associated with the current healthcare practice [11, 12]. Fragmentation refers to the fact that an individual's healthcare information may reside in various healthcare organizations that they visited previously. As has been observed in this study, chronic care patients may have routine medical visits with both their primary care physicians and various specialists. Patients who have severe diseases tend to consult multiple experts to pursue the best treatment or obtain second opinions constantly. Many times, past medical records are not accessible at the point of care. Even though we advocate universal Healthcare IT solutions to interoperate different systems in different healthcare organizations, many technical, financial, organizational and political barriers remain in constructing such a universal accessible record-keeping system.

In the current study, the patients' self-maintained medical records shifted record management from provider-centric to patient-centric. The records are no longer kept at a single healthcare organization, but are organized by an individual patient across various healthcare organizations. This individual-based management allows patients to process their life-long medical records and keep information with them conveniently. This concept is much like the integrated online PHR system that incorporates patients' life-long medical records in a safe and secure place [4]. However, the integrated PHR requires huge input from both the providers' side and the patients' side. It requires go-live EMR systems that store patients' information at the providers' side and also Internet access and computer literacy at the patients' side. This study was conducted in an under resourced healthcare settings with many patients who are uninsured and suffering from poverty, yet even in this setting, the patients were capable of managing their own healthcare records. This study proves the values of personal records management from the individual patients' perspective.

Patient-provider Communication

Patient-provider communication is the basis for outpatient practices. In common occasions, patients have to verbally report their symptoms and other medical histories to doctors and continue answering questions that doctors raise. Thus, the quality of the healthcare relies on whether patients can accurately express their needs and answer questions. This, however, may be challenging for those who have low health literacy and educations [9, 10].

Many patients in this study were elderly and suffering from memory loss, and may not have been able to understand what the doctors asked them. In turn, most of times, what they communicated to doctors was generic information about their health. Such as the example showed in the previous section, even though the patient and his mother described the injury incident to the doctor, the information they reported used lay words and may not have satisfied a physician's professional needs. The inaccuracy of self-reported information may be error-prone and lead to medical mistakes.

This verbal communication has been replaced by sharing medical records in this study. Patients always submit their recent medical records book for review before they enter the consulting room. The initial inquiry has changed to a records review session where records from different organizations and time spans are read by doctors. During the medical interview, patients always refer back to their previous records to help answer questions. We have observed many occasions where patients facilitate doctors to locate specific information in the record books, such as one individual lab test result or a particular medical visit. Patients may even bring in records that were obtained many years ago in case it is needed in the consulting process, though this is most often seen when patient present with serious diseases.

This information sharing differs from patients' verbal conversation since medical records are documented by healthcare professionals. In this way, a patient's healthcare information is transmitted among healthcare providers without any alteration. This fosters invisible collaborations among various doctors, across different times and locations. Even though these doctors may never meet, they can use the shared records to collaboratively make their judgment and speculate about earlier disease situations in a way that would otherwise be unavailable to them.

Patient-Provider Collaboration

The shift to a medical records system also affects how physician and patients communicate. Patients often stay passive in the healthcare process. They wait passively for healthcare professionals to collect and review their healthcare information and make their decisions. By managing their own medical records, patients are taking more responsibility since the goal of obtaining good health now requires their involvements. They have to transmit appropriate medical records to their providers in order to guarantee quality healthcare. In this sense, a simple task of carrying medical records to the hospital is participating in one's own health.

By transmitting medical records to healthcare providers, patients start forming a collaborative relationship with their doctors as how they manage their records affects their own health outcomes. Accordingly, the job of organizing pieces of information in the thick medical records is also shifted from the providers' side to patients'. Many patients in our study took the effort to reorganize the scattered information into a mean-

ingful arrangement so that it was easy for physicians to check during the consultation. Patients not only facilitate the timely access to medically relevant information in a time-constrained situation, but also ensure the all the necessary medical information is checked to avoid confusion. These involvements enable patients to be engaged in their own healthcare by supplying medical information at the point of care to ease the information flow in medical interviews.

Control of Personal Health Information

Self-maintained medical records also provide patients with a strong sense of control over their own health information. Patients can choose to show or not show certain records to their physicians. For example, one observation in the study showed that a patient hid some records at the beginning of the consultation and showed it later on. This was because the patient was obtaining a second opinion. He hid previous records so that the doctor could provide him with fresh insight.

Patients also have control over how they keep their records. As some observations described earlier, some patients prefer to have recent records in their purse at all times in the case of impromptu medical visits. Many others keep their records in separate piles, for serious and mild diseases, organizing which records to bring to which providers. Patients also integrate health information that is generated from home with the information they obtain from the hospital, such as organizing home glucose readings with clinics results chronically, or associating lab results with a food diary that account for activities in the same time period. Hence, the full access of medical records enables patients to engage more fully in using their health information, and eventually in their own health.

Conclusion

This paper explores how patients' self-maintained medical records affect clinical practice in consulting rooms. We conducted an observational field study at an urban Chinese hospital to examine how personal health records are shared and used during medical interviews. The observations reveal that self-maintained records are largely used as a transitional tool for patients to share information with healthcare providers. This sharing process allowed patients to integrate their health information in a patient-centric way and provide them with a strong sense of ownership and control over their own health information. Self-managed medical records changed error-prone verbal reports into professional documentations collaborated among providers. Most importantly, this study shows that patients, even those who have low health care literacy in under resourced healthcare settings, can be effective contributors to their own health. Researchers ought to rethink the patient-provider relationship in designing new interactive health systems that force patients to take more responsibilities in the healthcare process.

Abstract

In this paper we discuss the fact that more and more patients are treated in their homes by a set of organizations, sometimes with different ownership, and how this fact places new and severe demands on health care and home service staff to communicate and collaborate. We point to the need for managers in different organizations to agree on ways of communicating and collaborating on the operational level and how this aspect needs to be considered during procurement of home care services. Most importantly, by reasoning around a set of problematic areas, we derive a set of related problems and suggest solutions for dealing with them. The solutions are a mix of organizational/administrative measures and IT support for communication and coordination.

Collaboration, Home care, Home health care, Home service.

Introduction

In Swedish health care more and more patients are treated and taken care of in their own homes instead of in hospitals or nursing homes. This includes severely ill patients who require several different professions to be involved in the care process. The involvement of many different organizational units, often with different owners, complicates the situation even further and creates high demands on collaboration and coordination among the involved care givers in order to achieve high quality care for the patient.

In an earlier paper [1], we described an investigation in two Swedish communities, Stockholm and Umeå. The results indicated problems in inter-organizational communication and cooperation in home care. Most of the problems were due to organizational and social obstacles resulting in a lack of communication among the units and individuals involved. In three subsequent papers [2, 3, 4] we have analyzed the requirements this places on collaboration and coordination. The findings stress the need for improved collaboration among managers and among staff at the operational level. In particular, managers from different organizations need to collaborate more effectively in order to set up goals and routines for collaboration. In addition, our results showed that collaboration has to be considered during procurement of health and social care, and that managers need to follow-up the quality of delivered services. The necessity for substantially enhanced e-services to support coordination and collaboration was also evident. The aim of the present paper is to explore further the needs for collaboration between different health care and home service units and professions, and to suggest organizational and IT-based solutions, based on a patient and process oriented perspective, focusing more on patient related processes than on organizational structures and processes. This focus involves:

- Arguments are grounded in the Understanding, holistically, the forces influencing how collaborative care processes should work;
- Identifying the need for new ways of communicating, and for mobile and immediate access to both medical and administrative information;
- Understanding the need for allocation and acceptance of different types of responsibility among the care givers;
- Suggesting changes in information support, which due to the nature of home care work has to be mobile and based on process-centered information models that support collaboration.

authors' previous research, i.e. on focus group meetings, interviews, questionnaires, observations and analysis of archive data conducted in the projects Intercare [5] SAMS [6, 7], MobiSams [8], VITA Nova [9] and VVP [10]. These studies focused on collaboration within and between organizations involving respondents with a long experience of health care or social care but varied experience regarding IT and IT use. The respondents were doctors and nurses from primary and specialist care, assistance assessors, IT strategists, managers, patients, relatives and representatives of patient organizations. More than 35 in-depth semi-structured interviews were conducted within the projects.

In the following we define how certain terms are used in this paper.

- ***Home health care*** involves:

  basic health care – provided by nurses or nurse auxiliaries, in Sweden the responsibility of municipalities, sometimes outsourced to the county councils' primary care units.

advanced health care – operated by the county councils, led by doctors and provided by multi-professional teams. This care often concerns severely ill children or patients in palliative care.

- ***Social care*** is personal care that involves help with the daily living activities (cleaning, shopping, feeding etc), and care that physically supports the patient (outdoor activities or personal hygiene). In Sweden this is the responsibility of the municipalities and may be provided by their own units, or by a contracted private company.
- ***Home care*** as used in the title of this paper denotes the combination of home health and social care.
- ***Patient care process*** is the sequence of activities carried out for the patient by health care or social care personnel and in which the patient and often his relatives/friends participate. The process can be seen as a project with the aim of producing better quality of life for the patient, while at the same time maintaining patient safety. Each activity in the project should contribute to create this value-based aim.

Collaborative home care

Two or more parties collaborate when they work together in order to achieve a common goal, i.e. perform a task that each one cannot cope with alone or at least not as well or to as low a cost. This implies that the mutual goal must be understood by all parties as well as the basic circumstances, demands and restrictions that the other party faces. Each party must be clear over how tasks are distributed and how ones own tasks contribute to the common goal. Thus, collaboration between organizations is a complex matter. Existing research has focused on a wide variety of aspects. In research concerning collaboration within health care, van Eyk and Baum [11] have studied what they name as interagency collaboration. Hudson [12] has studied joint commissioning across the primary health care-social care boundary in the UK. El-Ansari et al. [13] have focused on public health nurses' perspectives on collaborative partnerships in South Africa. El-Ansari et al. [14] investigated collaboration and partnership and the problems with measuring collaborative outcome. Lichtenstein et al. [15] have studied the effect status difference has on individual members in cross-functional teams. Mash et al. [16] have studied team learning in healthcare that sees the organisation as a living system in which information flows. Participation and the development of team work are key aspects. If managers of the health system wish to enhance organisational change, then their goal may need to shift from optimizing health care delivery in a mechanistic model to optimizing health care workers in a living system.

In the field of mobile work and information processing, Ammenwerth at al. [17] explore how mobile artifacts can be used for information processing in a hospital. Pascoe [18] describes how mobile artifacts increase the amount and speed of data being recorded in everyday work; Najjar et al. [19] describe how wearable computers might increase the performance of quality assurance inspectors. Guerlain et al. [20] describe personal information systems for roving industrial field operators, and Heath and Luff [21] examine the ways in which mobility is critical for collaborative work.

When several parties collaborate it may be difficult to formulate one single objective, since each organization has its own goals. It is, however, important that all involved are aware of the overall purpose of the activities concerning an individual patient and make sure that this is in accordance with their own and with the patient's goals. Cooperation needs to take place both at the top and at the middle management level and among the staff carrying out the care. These levels exist within all health and home service organizations.

Some problems and suggested solutions

There is not much research dealing with the problems of collaboration in home health care, their causes and effects. Apart from works by Winge et al. [3- 5], one example is Åhlfeldt [22] who, based on interviews with health care staff and patients, derive a set of information security related problems in connection with collaborative care. Most of these are related to administrative routines and policies, not to technology. Åhlfeldt and Söderström [23], discuss the need for coordination in collaborative home care. They call for a "coordinator" with an overall responsibility for the patient's care planning. On a more general level, one well-known problem as organizations grow concerns administrative specialization and integration [24]. Health care is also subject to medical specialization, which places special emphasis on the need to coordinate units and professions. Horizontal organizational coordination is, among other areas, addressed in attempts to improve the logistics of Swedish health care (for example national projects to improve accessibility and shorten waiting times), while vertical coordination is a common problem concerning for instance control and feedback systems of work environment, quality and economy. One problem in integrating vertical and horizontal levels can be found in relation to the optimal use of management systems (see for example [25]).

Laws and regulation

Non-existent or inconsistent regulation results in improper routines and policies for cooperation, in poor awareness among those involved and in inadequate compensation systems. This in turn causes inadequate collaboration.

Suggested solution: Revise and re-phrase laws and regulations so they facilitate and insist on real collaboration.

Management and coordination

If managers at different levels do not understand what is required or cannot explain the aim and reasons for collaboration - and clarify which specific collaborative actions that are required - the operational staff will probably be discouraged from performing such actions. Managers of the collaborating units must find ways to explain how the care process as a whole is intended to function and what requirements it imposes on collaboration in order to be both effective and efficient and produce good quality for the patient. If this care model is vague to managers it usually leads to a poor understanding of the way collaboration needs to work on the staff level.

Suggested solution: Managers need to clarify for themselves and others what the holistic organizational mission involves when it comes to collaborative home care; explain what is

required and why; give accurate directions; provide convincing explanations as to why certain coordination and collaboration activities are necessary and provide standards for how they should be conducted. The situation of the patient is the foundation for collaboration between health and social care. A shared plan for the patient process must be produced with the focus on safe and high quality care. The plan should enable a follow-up of the results of the care. In each individual case, the goals of the patient process need to be explicitly formulated and based on the needs of the patient, while the staff has to be trained to always consider the goals of the process.

One of the reasons for poor collaboration is that care staff is not aware of other care staffs' actions and plans. Then activities cannot be coordinated and resources cannot be optimally used. In some cases this may also increase the risks for the patient's safety.

Suggested solution: Information services have to be developed to inform all actors directly of what is relevant for them to know about the patient and the planned and performed activities. This solution needs the clarification of goals and roles. Based on a well functioning care plan, actions can be coordinated so that work distribution will become more optimal.

To bring about collaboration in care is demanding. Health and social care that does not consider requirements for collaboration leads to poor quality and bad utilization of resources.

Suggested solution: Requirements for collaboration and co-ordination must be taken into account during procurement of care services. This includes clear descriptions of services needed to support collaboration for all involved. To achieve this, health care procurement units have to be trained in line with the new care model and in collaborative work. New strategies for follow-up of care are needed, also concerning the process and effects of collaboration.

Concepts and terminology.

The ability to provide the right information when needed, presented in a way that is understandable to all actors, requires well-defined concepts. Unclear or ambiguous concepts lead to a lack of understanding of what information is needed amongst all actors throughout the whole care process. Ambiguously expressed concepts in medical records present risks for the patient. Information requirements cannot be expressed clearly, increasing the risk that information systems will not provide the information needed for coordination and collaboration. Different units and professions offer varying competencies, perform different tasks and see different aspects of the patient. Ambiguous concepts make communication less effective, which in turn obscures coordination and collaboration.

Suggested solution: The concepts have to be identified on the basis of the patient care process. Collaboration has to take place with the patient and his needs in focus and be described on the basis of models involving care and collaboration strategies. The care model needs to define how collaboration should be carried out. The distribution of responsibility must be clearly described. Concepts that are involved in the process should be defined in an information model, and all of this set in a relevant context. It is particularly vital to define concepts that are important for patient safety and for communication between various kinds of care units.

Lack of collaboration may be caused by a poor understanding of what it is that characterizes the collaborative care itself on behalf of the health and social care staff as well as the patient and next of kin. This aspect concerns the situation when it is not clear what the involved units actually should do and how they should take each other into account, e.g. a lack of understanding of the role and responsibility of a unit for "advanced home health care" in relation to hospitals and primary care. Also, the patient and his relatives may sometimes feel that he has been sent home and left abandoned.

Suggested solution: The strategy for collaborative care should be described and clarified on the basis of a common health care and home services process. The need for shared information should be identified and then defined in a common information model for future IT systems. This will clarify responsibility, facilitate planning and collaboration, improve patient safety, and make it possible to monitor the care across organizational borders. The clarification of the collaborative care concept must involve management levels and staff and involve ways to deal with old routines and habits that might be hard to change.

Motivation and inter-organizational team-work

Low motivation due to lack of clear goals and feedback, role ambiguity, fragmentation of tasks etc. on behalf of the operational staff may lead to less commitment to collaboration. Furthermore, care staff may have little knowledge of, or in some cases be less interested in what other units do with the patient. Such awareness is, however, important in order to develop effective and quality-oriented collaboration.

Suggested solution: A new and better reward system for cooperation is needed, allowing for economic compensation and allocating resources for collaboration. Responsibility has to be clearly distributed among actors so that everyone has a basic knowledge of who is doing what. IT services are needed that support the patient process, staff interaction and feed back processes. The staff can be motivated through participation in planning the individual patient process. Doing so they can understand how their own work contributes to better collaboration and fulfillment of patient needs. Organizational responsibility has to be clarified, also concerning managerial decisions. Political and strategic leaders need to realize this and provide means for collaboration. Representatives of care staff from each involved care unit should participate in constructing a joint care plan for individual patients. This will make them understand how other actors' activities contribute, in a coherent set of tasks, to the realization of patient goals. Information support for care staff will provide a better understanding of which actions that lead to particular goals. There is also a need for better coordination of the individual patient process per se. New e-services for care-planning can support this function, optimally a common responsibility of a virtual team. The e-services must include support for quick changes in the patient's care plan.

If goals for the patient process are not clearly formulated it is difficult to coherently provide activities from several care units. There will be no basic ground for adapting and understanding

information concerning what other units do in order to reach the goals of the patient process.

Suggested solution: Formulate a set of goals for each single patient process when new essential needs of the patient occur together with the patient and/or his relatives. State clearly each care provider's responsibility. A well developed IT-based care plan, including coordination support, is an instrument that all cooperating units can access. The organizational members' own responsibility to seek out this information should be clarified and supported from the organization.

Collaboration across organizational borders is a prerequisite for good teamwork among various professions and with the patient and his relatives or friends. Lack of collaboration easily leads to bad care quality, feelings of insecurity and actors being uninformed about the patient's condition. At worst, the patient's health may be at risk. Lack of collaboration and agreement on the management level about the requirements of collaboration may lead to procurement of care that does not take collaborative aspects into account. It may lead to bad utilization of resources, e.g. the same activity is repeated several times or in a less than optimal order.

Suggested solution: Train team members in reading documentation originating from other units (provided that security allows it) so different actors can see patterns and signs at an early stage. Provide an information support for this. This will achieve more timely actions in meeting new needs of the patient and a better anticipation of problems. Collaboration supported by good IT solutions will increase safety for the patient and make him less prone to take unnecessary contacts with the care team. It will also facilitate a good utilization of resources. Routines for measuring and following up provided care should be implemented on the basis of evidence based competency, i.e. ability to judge how care ought to have been conducted according to goals, or if one had realized early what was happening when something went wrong.

Summary

To summarize, improvements are needed among all involved parties, from the top and middle managers to operational staff. The suggested solutions are a mix of development of care and collaboration concepts as well as organizational measures and IT support, and most importantly, the establishment of a new strategy and a new care model for collaborative health and social care. This involves:

- the need for managers in the involved organizations to define and agree on goals, rules and routines for collaboration on all levels,
- the need to include requirements for collaboration already in the care procurement process,
- the recognition of the importance for coordination among care givers and care activities,
- the need for awareness of and clear goals for each individual patient process.
- the need to clarify how care results shall be described, what results to follow up, and how this should be done.

Thus, the presented solutions address and try to improve vertical and horizontal coordination within and between organizations.

How IT may contribute

Unclear or ambiguous concepts are a problem in the entire health care sector. Even the most central terms can be understood differently among different stakeholders. We believe that to a certain extent this is something to accept and learn to live with. In the context discussed in this paper it is, however, desirable at least to agree on terms and concepts that concern collaboration. The models, primarily information models, developed in the projects mentioned initially [5-9] are important contributions to this issue. These models are based on a process that describes important information exchanges around the patient, regardless of which organization that is responsible. The projects also resulted in explicit knowledge on how improved and patient-centered collaboration among care providers can be accomplished, mainly through an enhanced way of working and a utilization of IT support that facilitate collaboration. The new ways of working should be described in process and conceptual models, which also form the basis for building IT support.

The SAMS and MobiSams projects also had the intention of clarifying the patient process, i.e. how it functions today, how the patient experiences it, and how it would appear with the suggested new ways of working and the correct IT tools. The IT support developed in these projects comprises a set of well defined e-services built to support coordination and teamwork. The services presently available concern tools for:

1. Planning and coordinating all work tasks during the entire individual care process, including formulation of mutual goals and objectives for all involved organizations and professions with the best interest of the patient in focus.
2. Definining the planned activities for each unit, in accordance with the agreed goals.
3. Allocation of tasks and resources for the planned activities, assignment of personal responsibility for the goal achievement of each task and definition of a procedure that measure and relate results to goals.
4. Planning and registration of the result of the care activities.
5. Registration of undertaken care activities in such a way that goal fulfillment can be assessed.
6. Conducting follow up and evaluation of the care process from the individual's point of view.

The tools were built in close collaboration with health and social care staff and implemented in a common test-bed where they were tried out together with new ICT techniques, i.e. stationary as well as mobile and handheld devices. The test-bed was set up to facilitate learning while developing collaborative care as a virtual enterprise, including the ways of utilizing IT.

Conclusion

In this paper we have discussed the increasing number of patients treated in their homes by many care givers and the

complex demands this new situation places on communication and collaboration among health care and home service staff. We have further pointed to the need for communication and collaboration on different organizational levels. In particular we have highlighted the need for managers in separate organizations to agree on ways to communicate and collaborate on operational levels, and how the need for collaboration and coordination must be considered during procurement of home care services. Most importantly we have, by reasoning from a set of issues, suggested solutions for how to deal with these demands. The suggested solutions are a mix of organizational and administrative measures, and development of e-services for communication and coordination.

Finally, we would once again like to stress the need for a new collaborative care model for health and social care with the patient's interest in focus and IT-tools as an aid. This model requires managerial awareness and the development of clear goals, against which results focusing on patient needs can be assessed and followed up across organizations. Even so, the challenge of implementing these ideas and changing the involved organizations, processes, routines and key actors will have to be furthered addressed.

Acknowledgement

The authors wish to thank VINNOVA (Swedish Governmental Agency for Innovation Systems) for sponsoring the projects that provided the basic data for this paper.

Barriers and facilitators that affect public engagement with eHealth services

Nicholas R Hardiker[a,b], Maria J Grant[a]

[a]*School of Nursing & Midwifery, University of Salford, UK*
[b]*Royal College of Nursing, UK*

Abstract

It is commonly accepted that public engagement with eHealth is beneficial. However, engagement is also variable. This article presents the findings of a review of published evaluation studies around eHealth services. A targeted search of MEDLINE, CINAHL and EMBASE returned 2622 unique abstracts. 50 articles met the inclusion criteria and were subjected to further analysis. 6 review articles were used for post hoc validation. Four main types of eHealth service or resource were identified: health information on the Internet; custom-built online health information; online support; and telehealth. 5 key themes emerged in terms of facilitators or barriers to engagement: characteristics of users; technological issues; characteristics of eHealth services; content issues; social aspects of use; and eHealth services in use. Recommendations arising from the review include: targeting efforts to engage those underserved by eHealth; maximizing exposure to eHealth across all sections of society; improving access to computers and the internet; appropriate design and delivery; ensuring content is relevant to different audiences; capitalizing on the interest in social computing; and clarifying the role of health workers in the delivery of eHealth.

Keywords:

Consumer health information, Informatics, Internet

Introduction

One commonly cited definition views eHealth as 'an emerging field in the intersection of medical informatics, public health and business, referring to health services and information delivered or enhanced through the Internet and related technologies. In a broader sense, the term characterizes not only a technical development, but also a state-of-mind, a way of thinking, an attitude, and a commitment for networked, global thinking, to improve health care locally, regionally, and worldwide by using information and communication technology' [1]. In common with this definition, other definitions also incorporate aspects of both health and technology. Health is generally represented as a process rather than an outcome, and technology is viewed as a means to augment, rather than replace, human activity. The tendency is towards optimism, with eHealth seen very much as an enabler [2]. It is a commonly held belief that public engagement with eHealth services is beneficial. The Internet facilitates widespread access to up-to-date health information [3, 4] and provides the means to obtain remote support [5, 6]. Telecare applications address an ongoing and increasing demand for care, resulting from an ageing population and a shortage of nurses and other health care workers [7]. However, public engagement with eHealth services remains variable [3]. This review of published literature seeks to formalize the reasons for this variability. This literature review forms part of a larger project 'Including everyone in electronic health information services'. The larger project, commissioned by the National Health service in England seeks to find out what help people need to use eHealth services. The aim of this review is to identify and explore factors (barriers and facilitators) that may influence engagement by the public with those services.

Method

Literature considered in this project included national and international academic and professional (i.e. non-academic) journal articles available from the three bibliographic databases, MEDLINE, CINAHL and EMBASE. The search strategy was developed in stages:

1) An initial targeted text search of MEDLINE (via OVID) using relatively obvious terms such as 'ehealth services', to find 'gold-standard' articles from which to harvest indexing terms i.e. Medical Subject Headings (MeSH) keywords.
2) Allocation of keywords, combined with OR, into three sets:
    a. Application e.g. Internet
    b. Service e.g. Consultation
    c. Evaluation e.g. Patient Satisfaction

    These keyword sets were combined with AND.
3) Fine-tuning of categorized keywords to ensure retrieval of (at least) all exemplar articles
4) Reworking of the strategy for use with CINAHL (via EBSCOhost) and EMBASE (via the National Library for Health, now NHS Evidence).

Searches were conducted in January 2009; they were not restricted by date. Each item (title, abstract, language and type)

from the initial search was reviewed independently by the two members of the project team (NRH, MJG). Items were selected according to the following criteria: an identified eHealth service; intended for use by members of the public; barriers or facilitating factors influencing use; readily and freely available online; and, published in English The following items were excluded: Commentary, book review, conference report, conference paper, conference abstract, editorial, opinion-based.

Review articles were not included in this review but were reserved for validation of the findings. Disagreements were resolved through face-to-face meetings. Agreed included items were obtained, allocated arbitrarily to the two team members and subjected to further analysis. A tailor-made data extraction tool, in the form of a table, was used to analyze articles into a number of categories, such as study design, findings, barriers and facilitators. Emergent themes that were common across different studies were identified via the completed data extraction tool and agreed at further face-to-face meeting.

Results and discussion

Four hundred and forty abstracts were returned via CINAHL, 1226 via EMBASE and 1153 via MEDLINE. After the removal of duplicates, 2622 items were considered in the initial review. Seventy articles were obtained for closer examination. Fifty of these were identified as meeting the inclusion criteria and were subjected to further analysis. The timeframe for included articles was 1999 to 2008. Six additional review articles, spanning 2001 to 2008 were reserved for post-analysis validation.

Type of eHealth service

The first set of themes to emerge from the analysis concerned the type of eHealth service featured in the articles. There were four main types:

1. Health information on the Internet (featured in 27 articles = 54%)
2. Custom-built online health information e.g. CDs, kiosks, portals (7 articles = 14%)
3. Online support e.g. coaching, mailing lists and online communities (12 articles = 24%)
4. Telehealth including remote consultation, monitoring and reporting (4 articles = 8%)

Little appears to have changed over the past several years in terms of types of eHealth service; in an early review of health information on the Internet, Cline and Haynes [3] characterized access to online health information in three ways: searching directly for information (corresponding in the current review with both 'Health information on the Internet' and 'Custom-built online health information'), participating in support groups (corresponding with 'Online support') and consulting with health professionals (corresponding with 'Telehealth').

Barriers and facilitators to use

The second set of themes to emerge from this review concerned barriers and facilitators. One hundred unique themes emerged. These were distilled into twenty seven higher-level themes, from which 5 overarching themes emerged:

1. Characteristics of users
    - Age [8, 9]
    - Educational attainment [9-13]
    - Ethnicity [10, 13, 14]
    - Health status [15-17]
    - Information needs [18]
    - Literacy levels [17, 19-21]
    - Motivation [11, 12, 17, 22-24]
    - Skills and knowledge [16, 25-29]
    - Socio-economic status [10, 11, 13, 26, 29, 30]
    - Trust [9, 17, 31-35]
2. Technological aspects
    - Access to resource [23, 26, 27, 29, 36, 37]
    - Operational issues [28, 38, 39]
    - Security and privacy [36]
    - Technological Issues [18, 40]
3. Characteristics of eHealth services
    - Access to information [32]
    - Content issues [9, 19, 27, 41-45]
    - Physical distance [22, 25, 31, 38, 46-48]
4. Social aspects of use
    - Belonging [31, 38, 46, 49]
    - Interpersonal issues [38, 49]
    - Reassurance [49-51]
    - Shared experience [33, 52]
    - Shared responsibility [39, 49]
    - Social contact [31, 47]
5. eHealth services in use
    - Empowerment [17]
    - Fit with everyday life [18, 23, 25, 26, 53]
    - People as enablers [25, 51, 54]
    - Usability and usefulness [16, 18, 22, 24, 27, 33, 55]

Characteristics of users

The findings suggest that both increasing age and low socio-economic status might be negatively associated with perceptions and use of eHealth services. Non-white ethnicity also appears to be a potential barrier. A literature review by Fogel et al. [4] on online cancer support groups found that African Americans were under-represented. There appear to be higher levels of eHealth service use among people describing themselves as white and among people of higher socio-economic status. Higher levels of educational attainment and literacy appear to be associated with increased awareness and use of eHealth services. Lack of motivation, interest and engagement, both in health in general and in eHealth, appear to be barriers to use. A lack of knowledge and skills around computer or Internet use appears to be barriers to the uptake of eHealth services, as confirmed by Cline and Haynes [3]. However, exposure to these services appears to improve both the perceptions of non-users and the frequency of use. Both health status and information needs play a less predictable role in engagement. For example, poor health status provides an impetus for individuals to seek information. However, poor health status may in itself inhibit an individual's ability and motivation to seek this type of support. Trust also appears to influence users' perceptions of eHealth services - opinion towards 'scientific' sources and researchers appears to be mixed - although it doesn't necessarily affect patterns of use. Trust

was identified as a significant issue also in the literature review by Fogel et al. [4]

Technological issues

Unsurprisingly, lack of access and poor access to computers and/or the Internet are significant barriers to engagement. Simply put, those with better access (particularly at home) are more likely to engage. Cline and Haynes [3] also recognized that access is inequitable. However, having good access does not guarantee use. Perceptions of users are also dependant on operational aspects of the service along with how it handles data security and privacy, as supported by a recent literature review by Botsis and Hartvigsen on telecare for older people [7]. Interestingly, security and privacy concerns did not feature significantly in many of the articles included in the current review.

Characteristics of eHealth services

As might be expected, and as supported by Cline and Haynes [3] the content of eHealth services is an important contributing factor to engagement. Important characteristics include: quantity, relevance (including cultural relevance), comprehensibility (both technical and linguistic), reliability and impartiality, navigability, flexibility and tailoring of content. Cultural relevance was also identified as important by Fogel in a literature review on ethnicity and literacy levels and Internet use for cancer information [6].

Social aspects of use

A decreased sense of isolation is seen by many as an important benefit of eHealth services, along with autonomy and an increased sense of control. Anonymity is also valued, although the impersonal nature of online communication might in some circumstances act as a barrier. Cline and Haynes [3] also acknowledged both a 'shifting balance of informational power' and the potential benefits of anonymity. People are often seen as important adjuncts to certain eHealth services: as gatekeepers, as enablers, as trainers and as coaches. A literature review conducted by McMullan [56] on the impact of Internet use on the patient-health professional relationship suggests three ways in which health professionals may respond to their patients as active consumers of health information: 1) re-assert their role as expert, 2) collaborate in obtaining and analyzing information, 3) guide patients to reliable resources. There appears to still be a place for direct face-to-face communication. To support this, Botsis and Hartvigsen [7] found that 'patients and nurses foresee the need for real nurse home visits along with telemedicine ones'. Social computing (e.g. online discussion and support groups) is generally seen in a positive light, providing a 'safe', flexible and personal environment in which to share experiences and responsibility, foster a sense of belonging, offer empathy and support, and gain reassurance. The review by McMullan makes a similar observation [56]. Active engagement appears to reap the most benefits.

eHealth services in use

Issues affecting engagement with eHealth services arise from their implementation and use. An obvious barrier concerns ease of use. An equally obvious barrier is lack of fit with everyday life, in terms of time, cost and technical or psychological factors e.g. unfamiliarity with the resource. A lack of perceived usefulness or relevance is a significant barrier to engagement with eHealth services. Certain potential users of eHealth services believe that information will make little impact on the status quo and may actually be a burden. Other users find eHealth services empowering, reassuring and supportive.

Conclusion

There are a number of recommendations in light of the findings of this review:

- Capitalize on the continued public interest in social computing and allow users of those services to reap the benefits of online community engagement
- Clarify the role of health workers in the delivery of eHealth services e.g. endorsement, facilitation, etc.
- Continue to focus on the appropriate design and delivery of eHealth services in terms of ease of use and fit with everyday life i.e. time and cost
- Attempts to maximize exposure to eHealth services across all sections of society, in order to increase familiarity and improve perceptions of usefulness and relevance, thereby maximizing potential use
- Make efforts to ensure that the content of eHealth services meets the needs of their target audience. Content should be understandable, relevant and trustworthy to a wide variety of potential users
- Make targeted efforts to engage those who are underserved by eHealth services due to age, ethnicity, educational attainment and socioeconomic status
- Maximizing exposure to eHealth services includes improved access to computers and the Internet

Barriers of Obtaining Health Information Among Diabetes Patients

James Milewski, Yunan Chen

School of Information and Computer Sciences, University of California, Irvine

Abstract

While healthcare information plays an essential role in the process of disease management, previous studies have shown that many patients may be unaware of the availability of certain healthcare information, thus leading to the progression of their diseases and deterioration of their health. This study explores the information seeking behaviors among patients with type-2 diabetes and explores the barriers that hinder effective healthcare information usages. 19 semi-structured interviews were carried out with patients and caregivers in various stages of diabetes disease management. Data analysis identified five major barriers for seeking health information: lack of motivation, passiveness, inconsistency of information, generality of information and loss of information. These findings call for the designing of active and personalized information delivery mechanisms.

Keywords:

Information management, Medical records, Access to information, Long-term care.

Introduction

The goal of achieving quality healthcare is a collaborative endeavor that requires input from both healthcare providers and patients [1]. Health information can educate patients to engage in decision-makings processes, understand their own health and actively manage their diseases. Yet, most healthcare information systems are designed primarily for physicians and other healthcare professionals [2]. Recent consumer health informatics initiatives advocate the role of patients in the process of obtaining and managing their own health information [3, 4], yet little is known about what support patient information needs [5].

Studies have found that many patients do not have adequate knowledge about their own diseases [6]. A study found that even for a common disease like diabetes, more than 50% of patients were unaware of potentially serious complications [6]. This raises the interesting question of why patients are not obtaining the vast amount of health information available to them.

Previous studies have looked into the topic of health information management and health information seeking behaviors among patients [7, 8, 9]. However, the focuses of these are mainly on information regarding homecare, such as glucose readings, magazine articles or patients' insurance information**.** Information about patients' encounters in healthcare settings is seldom considered as part of the health information seeking and management process. As various healthcare providers typically operate as separate "silos" without including patients in the healthcare process [10], seeking and obtaining one's own medical records should also be part of the health information seeking process.

In this study, we adopted a boarder view towards personal health information so as to include both the information gathered by patients, e.g. magazine articles, homecare diaries and information produced in healthcare settings, e.g. lab results, diagnoses and other clinical documentations. Since homecare information is produced by patients at home, there was no need to intentionally seek out it any more. Therefore, the scope of information seeking in this study focuses on Medicare information and external educational materials. We chose to study information seeking behaviors among type-2 diabetes patients. There are two reasons for this choice. First, for diabetics, obtaining health information and staying informed is crucial for maintaining self-care, where not only glucose levels, but also diet and exercise have to be controlled by patients themselves. Second, as a common disease, information about diabetes is readily available for patients. This eliminates the possibility of not having enough resources to look for health information. By limiting this study to one disease we avoid the influences of individual disease characteristics in the information seeking process. Due to the space limit, this paper we only introduce the findings regarding health information seeking behaviors and the implications of them for health information system design. The information management behaviors will be presented in our future work later on.

Methodology

We conducted 19 semi-structured interviews with patients with type-2 diabetes and their caregivers, such as family members or friends between June and September 2009. IRB approval was obtained from the university before the research work started. All the participants were recruited at an outpatient clinic located in southern California. One author was stationed in the patients' waiting room during the regular clinic hours and inquired patients if they were willing to participate in our study. We also left flyers in the front desk of the clinic with the researchers' contact information. Each participant was compensated with 40 dollars for their time.

As mentioned in the introduction, for this study we adopted a broader view towards personal health information where both health information generated in healthcare settings and gathered by patients at home are considered personal health information. Interviews often started by asking for the patients' own journeys about their diseases, followed by a series of questions regarding health information needs, information seeking and diabetic management behaviors. Table 1 lists the main categories of the interview questions. Each category of questions was probed further according to patients' responses.

Table 1 – Interview protocol of the study

Interview Questions:
Where do you obtain diabetes related information?
Do you think there's enough health information available?
What are the challenges for you to search for health information?
Do you request of copy of your medical records after medical visits?
What technologies and tools are you using in managing health information and diseases?
Other behaviors about dietary and exercises?

The interviews lasted approximately 60-minutes in length and were audio-recorded for further data analysis. All the interviews were conducted at the patients' homes – presumably an environment where they naturally keep their health information and engage in disease management activities. Since the interviews were conducted at patients' homes, occasionally family members would join the conversation or provide information upon participants' requests. Unless caregivers were interviewed separately as an interviewee, we counted the spondaic discussion with family members as one interview. Digital photos were taken (either during or after the interview) as tools and materials related to disease management, capturing the context and location of the artifacts.

Constant comparative method [11] was used in the study to extract different themes from the interview data. This method allowed the authors to use an iterative open coding strategy to summarize main themes from the data. The authors coded the text to break down, compare, and categorize the data into initial categories, and then further developed these categories into themes.

Results

We interviewed patients in different disease stages, from the recently diagnosed to those who suffer from multiple complications. The number of years the patients had been living with diabetes ranged from 3 to 39. Echoed with what we speculated in the earlier section, most participants believed that health information is radically available for them and that there is generally no difficulty obtaining such information on their own. However, purposely seeking that information seemed rare among the patients. In this section, we describe general information seeking behaviors, and introduce the barriers to information seeking that are identified in our analysis. We will then discuss the implications for designing systems to overcome these barriers. The findings presented in this section are generalized from major participants and represent the common concerns across all the patients we spoke with. Therefore, these findings indicate behaviors and challenges that can be generalized to the broader population of diabetes patients, and perhaps even to other chronic diseases sufferers.

In general, the diabetes patients were satisfied with the amount of health information available to them. No one in the study mentioned any difficulty seeking information on diabetes. 17 out of the 19 participants believed it was fairly easy to obtain health information. In addition, many patients believed they encountered more diabetes related information in their daily lives than in the recent past 5 years. This showed that at least for diabetes, a lack of available health information no longer hinders how patients seek and obtain health information. Healthcare providers are the major information sources for most patients, where they either pick up brochures in the waiting room or receive health information from providers. Other than healthcare providers, social networks are another important information source as a few patients claimed that they obtained information by "*play by ear*". About half of the patients search for health information on the Internet.

Although almost all commented that there is enough health information available for them, many patients admitted that they didn't engage in information seeking and disease management activities. Our analysis identified 5 barriers to understand the breakdowns in the information seeking process.

Motivation Fade Overtime

Interviews indicated that patients' health information needs are maintained largely on a "need to know basis", meaning they seldom look for health information to educate themselves unless they have been diagnosed with new complications – at which time it is impossible to revert to their previous health status. Most patients started collecting health information when they were first diagnosed with diabetes but discontinued the learning efforts shortly after they had a basic understanding about the disease.

> *Ah, well, ah, I think that it was since they told me I had diabetes. Both of my parents are diabetic. I saw them taking pill after pill. I don't want to see myself like that. At the beginning, I did the medications. You know. I did what I had to do. But now, I'm tired. I'll do it tomorrow. I'm at the point where I don't care much about anything.* (U05- line 118)

> *When I was first diagnosed because I want to know exactly what it is and how it affects me.* (U19-line47)

During the motivated information seeking stage, patients actively searched for health information in order to understand what diabetes was and how to manage it in general. Patients' motivation to seek healthcare information gradually faded overtime; many mentioned that they stopped reading and looking for new information after a couple of months.

However, the course of diabetes changes overtime. The health information patients obtain at the early stage of their disease may not be sufficient for the later stages of disease management.

This lack of motivation for health information seeking is partially a result of the misconception that diabetes is a stable illness and that there is no need to continue to learn more. Patients tend to believe that what they have learned should be sufficient for their disease management once they have a pretty good knowledge about diabetes. Lack of motivation also comes from the extremely long disease management process of an illness like diabetes. It is well known that there is no cure for diabetes, and once diagnosed, patients will have to deal with it for their entire lives. It is easy to feel motivated to learn to manage the disease, but it is challenging to continue to engage in information seeking activities. This explains why the patient's feeling of tired and not caring it anymore.

Passively Seeking Information

Many patients use "*accidentally*" to describe the way in which they seek health information. "Accidentally" means they seldom initiate the information seeking process, but pick up sporadic health information that they happen to see or hear. Most patients commented that other than their physicians, they accidentally read a few articles in medical journals placed in patient waiting rooms, or that they happened to get a few flyers about diabetes in the mail or read about it in the newspaper. "*Play by ear*" was also quoted by many patients indicating that the information picked up among their social network was a major source for them to learn diabetes management.

> *[I] Usually get our stuff from the clinic, like the pamphlets lying around. (*U04-line 52*)*

> *Ah, [information seeking is] not too complicated. It depends. You have to talk with your doctor. It depends if you have a good doctor at the time. (*U12-line152*)*

This passiveness reflects on the information sources where the patients obtain the healthcare information. Patients pick up information that happens to be available to them; *Accidentally*, *play by ear* or picking up things *lying around* all indicate the passive nature of patients' information seeking behaviors. They seldom initiate active information searching on their own but passively wait for information that happens to "be there". This passiveness indicates that patients may not obtain a comprehensive understanding about diabetes since they only receive information piece- by-piece from different sources.

Inconsistency of Information

Even though no one in the study thought obtaining information about diabetes was a difficult task, 6 out the 19 patients commented that occasionally the information they saw was conflicting. New information may conflict with what was learned from their providers, articles they read or their own experiences as patients.

> *I'm not real happy about a lot of the diabetic stuff that is out there. The diets and different things that they tell you have things like high fructose corn syrup in them and different things. I'm reading the ingredients and going, "ewhhhh," I would never put that in my body. Even on a regular basis I wouldn't do those things. There are a lot of things out there that I don't agree with at all. (*U08-line 110*)*

This quote shows that even for the small number of patients who are willing to actively seek health information, conflicting information discourages them from continuing seeking it since they don't know whether they can trust the information given to them or which information they should they trust. The quality of health information, therefore, hinders the way patients approach healthcare information and sometimes leads them to turn away from engaging in the active information seeking process.

Generality of Information

"Too general" is another term that was repetitively used by patients during the interviews. When being inquired about how they use healthcare information they picked up, most patients replied that they seldom read or use it. Although information about diabetes is available almost everywhere, it was often too general and only covered things they had already known for years.

> *Most of it I would say is irrelevant to my situation. All of them say don't eat a lot of sugar. You don't have to tell me that. (*U03-Line 73*)*

> *Ah, most of the information we get, we are already aware of at this time. So it's just like a reminder for me…. It's pretty clear and, ah, easy to remember because time and time again it's the same. (*U10-line 89*)*

The flyers and brochures patients collect in waiting rooms usually target newly diagnosed patients, with a hope to educate them about what diabetes is and common complications. However, most of the patients in our study had already gone through the initial learning stage of their illness and often found this information useless for their situation. As shown in the quotes, patients already know not to consume a lot of sugar and already know basic information about the illness and the importance of keeping their glucose in the normal ranges. The heath concerns that bother them currently are more specific, regarding complications they have or questions they have regarding the balance of medications among the multiple diseases they have. None of these issues can be found in brochures in patient waiting rooms or in their social networks.

Loss of Information

One question we explored in the study is whether or not diabetes patients seek the health information generated during their medical visits, *e.g.* information in medical records. 11 out of the 19 patients claimed that they keep a copy of their records at home, indicating a high awareness of owning medical records. However, further probing of this issue found that patients usually only have copies of their lab results rather than their entire medical records. Information such as written diagnoses, prescriptions and clinical notes are almost never pursued by patients at all. Nevertheless, when asked if they were willing to have a copy of their entire medical records, most patients said yes without hesitation. For them, keeping

medical records is way to track the process of their diseases and be more aware of their own health issues.

> *Yes. I would like to know [information in the medical records], uh, to see what it was like. What is was like a year ago. Say, six months ago it was like this and then this happened or this is different. I guess it is just like to compare for myself how is my diabetes going (*U05-line 35*).*

It takes time and effort for patients to request the information that is produced during medical visits and patients often feel frustrated when they don't have control over the information in their records. None of the participants in our study have their entire records with them. Yet, the information in medical records plays an essential role in coordinating patients' healthcare among different providers.

> *I'm a contractor. I move around from state to state so I have to get a new doctor in a new state… They all want to start me over again at 10 units… I usually lose it [medical records]…I always feel unfortunate that they don't have a database that the doctors could feed it in, the web or something (*U03-Line 17*).*

As indicated in the above quote, information loss in transiting from different healthcare settings or from healthcare setting to patients' home may cause serious interruptions in the healthcare process. Some patients mentioned that they don't remember what doctors told them during the medical consolation. During consultation, some patients take notes about what they have been told, more just rely on their memories - a way that is presumably error-prone and easily leads to loss of information.

Discussion

The 5 barriers indentified in our study can be divided within the following categories: 1). passiveness and lack of motivation of the patients 2). non-specific, inconsistent health information and 3). loss of information produced in healthcare settings. In this section, we discuss the implications for designing future healthcare information tools to overcome these barriers.

Designing active information delivery system

Our study found that patients' motivation for seeking health information fades shortly after they obtained a basic understanding of their diseases. Yet, patients are not resistant to the healthcare information that is available to them despite seldom actively searching for it. This information seeking behaviors indicates that the design of health information portal should actively fill in sufficient health information to patients, especially at the very beginning of disease onset stage and then persistently motivate patients with new information. Doing so allow patients to obtain health information effortlessly. The health information sent to patients should be done on a long-term basis to keep them aware of the health risks throughout the course of their disease.

It is notable that online healthcare portal shows great potential in delivering health information actively to patients. A few of the Internet users mentioned that after subscribing to various online diabetes websites, they constantly receive health information. One patient told us: *I get a lot of things on there. I have to screen them quite a bit* (U18-line 39). However, the conveniences of the regular online information delivery are discounted when information are not specific to patients' individual needs. They may also overwhelmed by the amount of information sent to them and choose to ignore it completely.

Designing tailored information delivery system

We also identified factors in the sources of healthcare information that discourage patients from engaging in effective information seeking activities. Patient often encounter repetitive information that is too general for their own health, or they don't know which information they should trust since various information sources conflict with each other. These findings suggest health information should be tailored to fit with patient's personal needs. Personalization holds great promise to transform healthcare from "standard care" to "personalized care."

Compared with generic information, information that addresses individual needs is more likely to be read and have an effect on health behaviors [12, 13]. A survey [14] on available tailoring mechanisms in healthcare found that most tailoring criteria used in previous studies are based only on one health behavior and possible stages of change such as nutrition, exercise and in this study, information about type-2 diabetes. However, what we found has proven that even this level of personalization is still considered generic information. Patients require more specific health information to address information that they do not yet know, such as how to care for certain complications, how to deal with the interplay of multiple chronic cares and new solutions for self-care. Tailored information has to fit with the patients' deepest concerns as well as provide new and trusted information that they have not encountered before. Health information personalization is one goal of future personalized medicine [15].

Integrating medical records with information delivery

Patients in our study seldom seek for health information documented in their medical records and leave this valuable information with providers. This behavior has caused information loss in the transition from hospital visits to self-care at home. Patients do, however, wish to compare their health issues in different time spans or transmit this information among caregivers. Integrating two sources of information will give patients a continued and complete view of their healthcare and keep them informed about their health issues. In addition to this, since most patients have expressed the desire to obtain specific information regarding their recent discomforts or symptoms, a system that matches outside health information with information on patients' medical records would allow patients to receive personalized information particular to the issues they are concerned about in a timely manner. Accordingly, the integrated information delivery would motivate patients in searching for more health related information and engage in disease management process.

Conclusion

This study explores health information seeking behaviors among type-2 diabetes patients and identifies the barriers that

prevent these patients from obtaining the healthcare information that is crucial for their disease management. These barriers fit under the categories of 1). passiveness and lack of motivation on the patients' side, 2). non-specific, inconsistent information available to patients and 3). loss of information produced in healthcare settings. An active and personalized information delivery portal that filters information based on individual needs and initiates information delivery should be able to overcome these barriers. Even though this current study targets diabetes patients, these findings may also be borrowed to direct healthcare information among patients suffering from other chronic diseases. This study is only the first step in an on-going project aimed to understanding patients' healthcare information seeking and management behaviors in the hopes of designing better information delivery systems in the future.

Abstract

This research paper examines the challenges in the development and adoption of an electronic patient diary within the Pathways Home for Respiratory Illness Project. This project supported community-based patients suffering from chronic obstructive pulmonary disease (COPD) to achieve increased levels of self-management and self-efficacy using electronic-monitoring techniques and mentoring by community health nurses. Participants had the option of voluntarily adopting an electronic patient diary to support their self-monitoring, which provided patients, nurses and clinicians with access to symptom and psycho-social data. This aimed to improve the identification, comprehension and initiation of early action in relation to alterations in their conditions. The paper presents data on technology adoption, electronic diary usage and, self-reported data quality, as well as examining the impact of the technology on hospitalisations (frequency and duration). The participants who chose to use the online patient diary continued their involvement with the project for the entire trial period (85% vs 54% completion). Participants were more likely to maintain use of the online patient diary than the paper diary. Both the groups experienced a positive improvement in their self-efficacy to self-manage their condition scores. The data highlight the problems implicit in some of the assumptions underpinning existing information systems models, especially in evaluating impact and the end-points presumed to be relevant in systems development life cycles.

Keywords:

Chronic disease, Self-management, Information technology, Symptom monitoring, Self-efficacy, Technology adoption, Electronic diary.

Introduction

Chronic obstructive pulmonary disease (COPD) is the fifth leading cause of death worldwide [1] and is the third leading cause of 'burden of disease' in Australia [2] with sufferers experiencing multiple co-morbidities [3]. Individuals experience escalating psychosocial changes and functional problems as the disease progresses [4]. These include difficulties with home management, restrictions on recreational activities, loss of independence and feelings of social and emotional isolation [5]. Additionally, people with COPD often have poor quality of life [4,6,7] and low self-efficacy for managing life with COPD, including symptom management [8]. COPD is more prevalent among men in lower socio-economic groups. However, reflecting the increased popularity of smoking by women in the second half of the 20th century, the rates of COPD for women are rising. It is anticipated that over the next 20 years death rates from COPD in women will overtake those in men [9,10,11].

Evidence exists to indicate that the quality of life of people with COPD can be improved and that morbidity and mortality levels can be reduced through a range of interventions including patient education, pulmonary rehabilitation, self-management of exacerbations [10] and a patient-centred approach to care provision [12,13]. These integrated chronic disease management approaches are increasingly focusing on improving methods for engaging and supporting the direct involvement of patients in their own care.

The Pathways Home for Respiratory Illness project is a collaborative project involving researchers from the University of Tasmania's Schools of Medicine, Nursing and Midwifery, and Computing & Information Systems. This project aimed to assist patients with COPD to develop self-management skills, mediated through increased self-efficacy for patient-identified health behaviours (Note: reference to 'self-efficacy' should be taken to mean 'self-efficacy to undertake self-management'). Self-efficacy is a core construct identified in Social Cognitive Theory [14]. This project was also informed by the Trans-theoretical Model of Change [15] through the awareness that individuals may vary over time in their motivation to enact behaviour change.

Bandura defines self-efficacy as: "people's beliefs about their capabilities to produce designated levels of performance that exercise influence over events that affect their lives. Self-efficacy beliefs determine how people feel, think, motivate themselves and behave. Such beliefs produce these diverse effects through four major processes. They include cognitive,

motivational, affective and selection processes" [16:*71*]. Thus, self-efficacy is the belief that one has the capabilities to undertake and complete a course of actions that are necessary to manage a given situation. Self-efficacy, is theorised to be an important predictor of whether one attempts the behaviour [17,18] and has been successfully tested within the domain of chronic disease self-management most notably by Lorig et al., [19] where positive improvements in health outcomes have been demonstrated through supporting self-efficacy.

Methods

Participants in the project were recruited while hospitalised with an acute exacerbation of COPD. They were then randomised into control or intervention groups according to the location of their residence with areas balanced for socio-economic and rurality factors. The quasi-randomisation was by domicile as community health nurses (CHN) performing mentoring were only located in certain areas. Participation was for a period of twelve months, with clinical and quality of life measures being recorded by a research nurse quarterly.

Upon discharge from hospital those participants allocated into the intervention group were linked with a CHN mentor who maintained regular telephone contact and monitored progress over a period of one year. Monitoring and responding to symptoms, a key self-management behaviour [20], occurred primarily via participants keeping a daily diary of their symptoms and any changes in them. The symptom monitoring diary was available to the participants in either paper or electronic format, with voluntary adoption of the electronic diary discussed with participants after an initial six weeks in the project. Participants were assisted with interpretation and understanding of changes in their symptoms by the CHN mentors. It was anticipated this would lead to more rapid and targeted changes in treatment. Mentoring was carried out primarily via the telephone, with electronic diary information made available to mentors via a secure internet site. The role of the mentor has been reported in a previous publication [21]. The inclusion criteria for participants were:

- Age over 45 years;
- Living in the catchment area –(Southern Tasmania);
- Diagnosis of COPD (based on COPDX Australia & New Zealand guidelines incl. use of spirometry [www.copdx.org.au];
- At least one exacerbation of COPD in the last 12 months;
- Passes a cognitive assessment with a mini-mental state examination score >21;
- Able to provide informed consent;
- Has telephone;
- No diagnosis of other active lung disease; and
- Not undergoing palliative care.

The project was approved by the Tasmania Health and Medical Human Research Ethics Committee (H8370).

During the initial stages of the project, information systems researchers utilised the project team's knowledge of COPD to make preliminary technology design decisions. Following ethics approval, a detailed understanding of the potential range of technological experience and expertise of participants was acquired through direct interactions with them. As recruitment progressed it became evident that participants would not utilise the full range of technology options that had originally been considered. All participants with COPD stated at recruitment interviews that they did not use the telephone for banking or similar purposes and they disliked IVR (interactive voice response) systems. Short Message Service (SMS) was also considered but the majority of the COPD participants had limited experience with mobile phones and/or had impaired eyesight and/or dexterity. These factors led to the decision that the only monitoring options would be paper and web-based patient diaries.

It was also considered preferable that the introduction of any IT tool should be phased. Thus participants were commenced with paper-based monitoring systems and migrated to the IT system if and when voluntarily requested. Migration to the IT based diary was implemented by information systems researchers in the team and facilitated by the CHN mentors and other research team members. Each participant's prior experience with computers was evaluated at an initial home visit by the IS team, when the online patient diary was demonstrated and their interest gauged. For each participant, training was provided in participant's homes, commencing with a basic demonstration and explanation, followed by lessons in turning the computer on and off and progressing to using the mouse. Due to the disease process, associated co-morbidities, ageing and underlying educational levels, participant education issues can be pronounced in the COPD population [22]. This was a major challenge for many of the participants and they were encouraged to use the mouse to play electronic card games to improve their confidence and dexterity. All participants were followed up with a telephone call the day after the computer installation to see how they were progressing and to organise a follow-up visit. At the initial visit the home environment was also assessed and the most appropriate location for the computer was discussed with the participants. At the second visit the participants were then taught how to connect to the internet via the dial-up connection and introduced to the project website. Use of the online patient diary and the longitudinal feedback were also demonstrated. A full computer screen-by-screen user manual was provided for the participants to follow when undertaking diary entry. Desktop shortcuts were provided to simplify the processes for the participants. Activities were monitored online by the IS team and further training or support provided as required or requested by telephone or home visit.

Results

A total of 106 participants were enrolled in the project, 51 in the control and 55 in the intervention group. The two groups were well matched and there were no significant differences between groups for baseline demographics, with the exception of gender, there being a greater proportion of females in the intervention group ($p=0.31$ by Chi-squared test). There was a

high attrition rate in both groups with only 68 participants completing the full 12 months, see Table 1.

Table 1- Control and Intervention Groups by Sex and Age

		Control Group			Intervention Group		
	Sex	**M**	**F**	**All**	**M**	**F**	**All**
Enrolment	**Number**	27	24	51	18	37	55
	Mean Age	71.1	68.0	69.7	70.2	64.6	66.5
Completion	**Number**	14	18	32	10	26	36
	Mean Age	70.6	67.2	68.8	71.6	64.3	66.6

In the intervention group, only 20 participants (36%) chose to use the online patient diary. A much larger proportion of those choosing to use online patient diary were female (80%), this was evident even though females predominated in this group. The mean age of those choosing to use the online patient diary in both the male and female groups was lower than those choosing not to use the online patient diary, see Table 2. In the IT Users group all those who did not complete the 12 months participation died prior to completion. In contrast only 27% of the Non-IT Users group died, the remaining (73%) withdrew prior to completion. Possible reasons for this difference are discussed below.

Table 2- IT Users and Non-IT Users by Sex and Age

		IT Users			Non-IT Users		
		M	**F**	**All**	**M**	**F**	**All**
	Number	4	16	20	14	21	35
Enrolment	**Mean Age**	67.8	59.9	61.5	70.9	68.4	68.8
	Number	3	14	17	8	11	19
Completion	**Mean Age**	65.7	61.1	60.2	66.3	66.7	68.0

The symptom monitoring diary was provided to all participants in the intervention group. The intention of the intervention was that the diary would be completed daily. The actual diary use was much lower than anticipated, with a total of 11,477 diary entries being received over the duration of the project from a possible 24,820 entries. As is evident from table 3 the diary usage was unpredictable. Although it is evident (Table 3) that the IT Users group displays a higher mean usage than the Non-IT Users group. Although these data are difficult to interpret due to the fact that people commenced the trial at different times over a two-year period and many of those who commenced did not complete their full twelve-month participation period. Further analysis may be conducted to calculate the number of days the diary was completed for those using paper or web-based entry and to express this as a proportion of the total number of days participants were active in the project. These will then be compared using Chi-squared.

Table 3- Total Symptom Monitoring Diary Usage

	Mean	**Range**	**Total**
IT Users	260.3	59-380	5,206
Non-IT Users	178.7	0-372	6,255

However, the differences between the groups becomes less marked when the analysis is limited to the diaries of those participants completing their 12 months participation (Table 4). The mean usage for the IT Users group equates to approximately 15 more entries than the Non-IT Users group.

Table 4- Completers Symptom Monitoring Diary Usage

	Mean	**Range**	**Total**
IT Users	285.2	83-380	4,849
Non-IT Users	269.9	49-372	5,128

A qualitative examination of the diary entries demonstrated little evidence of differences in the quality of entries between the IT and non-IT users. The hospital utilisation raw data reveals that the IT Users group had more admissions to hospital (Table 5). However, the average length of stay for the IT Users group was 1 day less than the Non-IT Users group.

Table 5- Hospital Utilisation Excluding Initial Admission

	Total days	**Mean length of stay**	**Admission Number**
IT Users	128.5	5.1	25
Non-IT Users	83.1	6.4	13
Total	211.6	5.8	38

Both groups demonstrated increase in mean mini-mental state examination over the period of the project. Essentially the mean MMSE scores were within the normal ranges: scores of 27 and above are considered normal; scores of between 23 and 26 indicate a borderline condition; and scores of 22 and below are abnormal. The minor increases in MMSE scores from enrolment to completion may be due to an initial adverse effect of the participants' exacerbation of their condition and subsequent hospitalization (Table 6). They may also reflect some variability within the measurements themselves.

Table 6- Mini-Mental State Examination Scores

	Enrolment			Completion		
Group	**Mean**	**SD**	**Range**	**Mean**	**SD**	**Range**
IT Users	27.2	1.7	23-29	28.4	1.7	25-30
Non-IT Users	27.1	2.5	22-30	28.0	1.7	24-30

The Stanford Self-efficacy for Managing Chronic Disease 6-Item (Stanford Self-efficacy) Scale is a validated measure of self-efficacy for self-management in people with chronic disease. As the Pathways Home for Respiratory Illness project was aimed at improving participants' self-efficacy for self-management this was a primary outcome measure. A calculated mean of the six items scored is the final Stanford self-efficacy score. Both groups demonstrated an increase in the mean and minimum Stanford self-efficacy scores (Table 7). However, the Non-IT Users group demonstrated a slightly greater increase than the IT Users group.

Table 7- Stanford Self-efficacy Scores

	Enrolment		Completion		Effect Size
Group	**Mean**	**SD**	**Mean**	**SD**	**Cohen's d**
IT Users	5.5	2.5	6.4	1.6	0.36
Non-IT Users	5.5	2.3	6.7	1.8	0.52

Discussion

This study has undertaken a preliminary comparison of the results from IT Users and Non-IT Users within the total intervention group of a clinical trial. The paper has considered outcomes that differentiate these two groups of users. These data will contribute to a forthcoming more comprehensive statistical analysis of the clinical trial and the quantitative impact of the online patient diary within the trial intervention. However, these preliminary results could be interpreted to provide evidence that the use of the online patient diary could be inhibiting the positive impacts of the intervention.

Previous studies, see for example [23] and [24], have indicated that computer use in the elderly is significantly influenced by gender. They found that males have greater computer knowledge, are more confident and less anxious about using computers than females. Interestingly this is not confirmed within this research data where females were much more likely to elect to use the online patient diary option.

In terms of demographic differences between the IT Users and Non-IT Users it appears that amongst the participants within the project the older age group, and particularly older males, were less likely to attempt to use the online patient diary. Those most likely to use the online patient diary are younger females. The participants who chose to use the online patient diary were more likely to continue their involvement with the project for the entire twelve-month period (85% vs 54% completion). All non-completions in this group were deceased. A similar number of Non-IT Users were deceased but 77.95% of those in the Non-IT Users group who failed to complete withdrew from the project. This suggests that participants engaging with the IT aspect of the project may have been more committed to the project although this requires further investigation. The data relating to the actual usage of the online patient diaries and the paper diaries does not provide a clear pattern of behaviour. Participants were more likely to continue to use the online patient diary than the paper diary. There was a marginally higher mean usage in the IT Users group than in the Non-IT Users group.

In relation to the development of self-efficacy to self-manage their condition using the Stanford self-efficacy scale both the groups experienced a positive improvement in their self-efficacy scores. However, the scores for the Non-IT Users demonstrate a greater improvement than the IT User. This appears to indicate that the use of the online patient diary impedes or limits the development of self-efficacy for self-management in people suffering from moderate to severe COPD. Alternatively it may indicate that those who were willing to take on change could adopt the online patient diary and develop self-efficacy but the degree of change was mediated by learning two tasks.

So what are the possible explanations for these findings? The most obvious is that the online patient diary and its use in some way interferes with the process of the mentored self-management. In terms of the Stanford self-efficacy scale the online patient diary appears to have weakened the positive effect of the intervention upon the development of participant's self-efficacy. This is possibly due to the additional learning burden of commencing to use the online patient diary. Alternatively, it is possible that the participants using the online patient diary have more regular interaction with their own symptoms, through the rapid online feedback; this may have raised their awareness of the limits of their self-management skills and as a result enabled them to reflect more critically on their self-efficacy than participants in the Non-IT Users group. In terms of acquiring skills that will assist in self-management behaviours during a life-time it can be argued that the online patient diary may have stimulated a more realistic assessment of participants' actual skills and knowledge.

Significantly, a qualitative analysis of a subgroup of the intervention cohort [25] has demonstrated that the introduction of the online patient diaries had a much broader influence upon the participants than was evident through the analysis above. These influences expanded to include the wider impact of the introduction of computers and the Internet into the participant's lives, the impact of changes in support networks from participation in the trial and the importance and impact of participation issues upon the participant's experiences of the trial [25].

Conclusion

Quality of life for those suffering from a chronic illness is "a product of complex interactions between subjective health, disability and the social environment in which the individual lives" (Anderson & Bury, 1988, p. 249). Thus, it is inadequate to attempt to understand the impact of any intervention in the lives of people with chronic illness solely in terms of generic instrument measurements.

For information system developers, this data highlights the need for more careful consideration of how the evaluation of impact in terms of adoption, usage and benefit is conducted. This paper also provokes the need for more complex analysis of the relationships that exist between clinical, social and technical measures of impact. For health informatics researchers there is also the challenge of the end-points presumed in the development of the technical systems produced to support patients to be able to self-manage – if self-efficacy is to truly be achieved then there is a need to be able to determine when the system is no longer necessary. Otherwise there is a danger of moving from medico-centrism to techno-centrism that artificially replaces one dependency for another amongst those we aim to support being able to self-manage.

Acknowledgments

The Pathways Home for Respiratory Illness project was supported by the Tasmanian Department of Health and Human Services and funded by the Commonwealth Department of Health and Ageing through the Australian Health Care Agreement 2005.

Abstract

Web-based interventions can be effective in changing behaviour of people faced with health problems. However, it is unclear whether they are effective in preventing health problems like overweight. The aim of this study was to investigate usage and effectiveness of the Healthy Weight Assistant (HWA), a web-based application to increase healthy behaviour in adults with a healthy weight or slight overweight, by means of a Randomised Controlled Trial (RCT). 297 respondents were randomly assigned to the intervention (n=147) or the waiting list group (n=150). The intervention group received access to the intervention for 12 weeks. At pre- and post-test we measured dietary and physical activity behaviour (primary outcomes) and BMI, knowledge, attitude, self-efficacy, subjective behaviour and insight in behaviour (secondary outcomes). All participants, regardless of group, show improvement in healthy behaviour and subjective assessment of healthy behaviour. People who are older, score higher on dietary behaviour and under-estimate their dietary behaviour are more likely to use the HWA. Using the HWA leads to improvement in physical activity behaviour and insight in physical activity behaviour.

Prevention, RCT, Use, Internet, Intervention Studies.

Introduction

Overweight is a problem in modern society. It is closely related to a number of chronic conditions, including Diabetes Mellitus type II, and places a great burden on the health care system. We all know that losing weight is not as easy as it seems. It might be more (cost)efficient to prevent people from becoming overweight [1-3]. To achieve this goal, interventions aimed at the general public are needed, which must not only inform about the risks of unhealthy dietary and physical activity (PA) habits, but must also stimulate to adopt healthier behaviour. Previous research showed that information only does little to change behaviour, while tailored and interactive interventions are more successful at achieving this goal [1,4,5]. A way to get these interventions to reach the broad target population is through the Internet. Furthermore, by using a web-based application, the content of the intervention can be tailored to the users and the intensity can be varied according to the needs and wishes of these users. Research has already shown the potential of these applications for the achievement of weight loss [6,7] and to some degree weight management [8]. However, most studies are focused on applications aimed at treatment or secondary prevention. Many questions remain on the effectiveness of web-based applications for the prevention of health problems. It is likely that interventions for prevention emphasize different problems than interventions aimed a chronic condition or an urgent health problem. The problem of attrition [9] might pose an even bigger threat to this kind of interventions, considering people who do not experience an urgent health problem, might have less intrinsic motivation to change their behaviour. Therefore, it can be argued that the intervention needs to supply this motivation to a greater extent. Previous research into the user experience of the intervention central in this study, which employed user centred evaluation methods, supports this notion [10]. It showed that improvement of the intervention should be aimed at enhancing motivation to (keep) use(ing) the intervention and to change behaviour. The recommendations acquired from the pilot study were implemented in the application. The goal of the current RCT is to gain insight into the effectiveness, usage and users of the Healthy Weight Assistant (HWA). By gaining insight into the effectiveness we hope to prove that the HWA is a useful tool to be made freely available to the general public in the Netherlands. Furthermore we hope to add to the scientific knowledge base on the requirements for successful web-based interventions in prevention. By gaining insight into usage and users, we hope to clarify the problem of attrition specifically for prevention, when the intrinsic motivation of users might be low. The ultimate goal is to tailor the intervention to user profiles based on the results of this study.

Methods

Intervention

The HWA is a web-based lifestyle intervention developed by the Netherlands Nutrition Centre, which is a government funded organisation aimed at improving healthy dietary habits and preventing weight gain in the general population. The goal

of the HWA is to support people with a healthy weight and people who are slightly overweight (i.e. Body Mass Index (BMI) 18-28 kg/m^2) to achieve and maintain a healthy weight. The aim is not to achieve a given weight loss, but to support the achievement of healthy dietary and PA behaviour. The theoretical basis for behaviour change via the HWA is the Trans-theoretical model [11]. The HWA consists of 4 stages: assessing baseline status; motivation to change behaviour; relapse prevention; goal setting and monitoring achievement of goals.

Design and Recruitment

Participants were recruited through advertisements about an online lifestyle intervention in local newspapers, supermarkets and on health-related websites. 297 respondents were interested in using an online lifestyle intervention and satisfied our inclusion criteria (BMI 18-28 kg/m^2; Dutch speaking). All participants were randomly assigned to either the web-based lifestyle coach or a waiting list. We used block randomization, stratified on age, sex and education with blocks of 4. A total of 150 participants were allocated to the waiting list group and 147 participants were allocated to the intervention group. Online questionnaires were filled out before the intervention period started and after the intervention period of 12 weeks. After this period, respondents in the waiting list group could use the intervention. The flowchart of the study can be found in Figure 1.

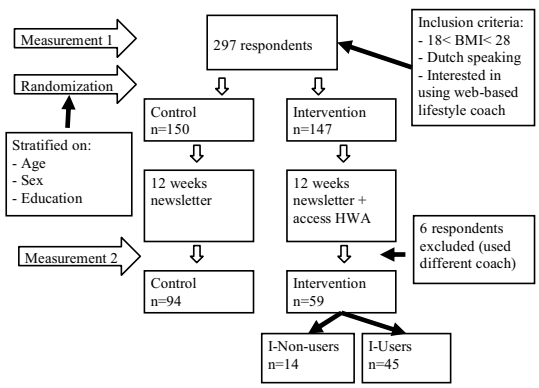

Figure 1 – Flowchart study

Research instruments

BMI was calculated using self-reported weight and length. Dietary behaviour was measured using a 14 item questionnaire [12]. Physical activity behaviour was measured according to the Dutch Standard for Healthy Physical Activity, using a 4 item questionnaire [13]. Self-efficacy for diet and PA were both measured using a 3 item questionnaire with a 5 point Likert-scale [14]. Knowledge was assessed using a 10 item true/false questionnaire based on the Netherlands classification model [15] (diet) and a 10 item true/false questionnaire based on the Dutch Standard for Healthy Physical Activity [16] (PA). Insight in behaviour was calculated by comparing the objective and subjective assessment of dietary and PA behaviour [17]. Questionnaires at baseline and follow-up were identical, except additional items in the follow-up questionnaires: the use of a (e-)coach other than the HWA (both groups); the number of newsletters received and opened (waiting list group); satisfaction with the HWA (intervention group). Satisfaction was measured using 4 items with a 5 point Likert-scale on user friendliness, usefulness, recommending to others and willingness to keep using the HWA [18]. In addition to the online questionnaires, log-files were used to attain the number of times each respondent logged on to the HWA.

Results

Descriptive analyses of baseline variables

As shown in Table 1, most respondents in this study were female (62.2%; n=181) and higher educated (51.9%; n=151). Mean age was 40.9 years (sd=13.8).

Table 1 – Baseline descriptives

	Control group	Intervention group	Total
Age (years)	41.0	40.8	40.9
Sex (% female)	62.7	61.7	62.2
Education (%)			
High	53.3	50.4	51.9
Moderate	31.3	36.9	34.0
Low	15.3	12.8	14.1
BMI (kg/m^2)	23.9	23.9	23.9
Reasons for use*			
Insight in lifestyle	56.6	63.5	59.8
Living healthier	40.7	47.6	43.9
Fun	40.0	44.4	42.1
Lose weight	35.2	42.9	38.7

* Multiple answers possible, so cumulative percentages do not equal 100%

Response rates

Of the 297 enrolled respondents, 159 respondents filled out the post-test questionnaire (response rate = 53.5%). In total the data of 153 respondents were analyzed to measure the effects of the HWA (Figure 1).

Usage and users

55% (n=77) of the respondents in the intervention group used the HWA at least once. Of these respondents, 53% (n=41) used the application only once. Mean satisfaction score was 3.0 (on a scale from 1 tot 5; sd=0.72). There were differences between respondents in the intervention group who used the application (users) and the respondents in this group who did not use the HWA (intervention non-users). Users were significantly older than intervention non-users (respectively 43 and 38; F=4.361; P=0.039). Furthermore, there was a significant difference on dietary behaviour. More users had a healthy diet (34.7%, n=26) than intervention non-users (13.0%, n=6; F=7.912; P=0.019). Lastly, the groups differed on insight in dietary behaviour. Intervention non-users were more often over-estimators (they perceived their behaviour as healthier than it objectively is) (28.3%, n=13) than users (16.0%, n=12; F=7.703; P=0.021).

Effect research

Pre- and post-test scores on outcome variables are shown in Table 2. Independent of group (intervention or waiting list), respondents significantly improved on dietary behaviour (F=7.548; P=0.007) and PA behaviour (F=4.189, P=0.042). Additionally, respondents perceived their behaviour as healthier on the post-test questionnaire (subjective assessment of dietary behaviour: F=8.559; P=0.004; subjective assessment of PA behaviour: F=8.008; P=0.005). Scores on attitude, self-efficacy and knowledge were high at baseline and showed no improvement.

Effect intervention

For the assessment of the effects of the intervention we compared the differences on pre- and post-test scores between different groups (waiting list, intervention non-users, users) as depicted in Table 2.

BMI, knowledge, attitude, self-efficacy, subjective assessment of behaviour

We can show no significant effect of the intervention on these variables.

Behaviour

The significant improvement on dietary behaviour cannot statistically be attributed to the intervention. As seen in Figure 2, both the waiting list group and the users showed improvement in the percentage of respondents who have a healthy diet. Intervention non-users did not show this improvement. There were no significant differences between groups. On PA behaviour, the differences between groups were more pronounced (Figure 2). Both the waiting list group and the users showed significant improvement in the percentage of respondents who showed healthy PA behaviour (waiting list group: Z=-1.964; P=0.050; users: Z=-2.500; P=0.012). This effect was greater for users than for the waiting list group. Intervention non-users did not show this improvement, the percentage of respondents with healthy PA behaviour even declined.

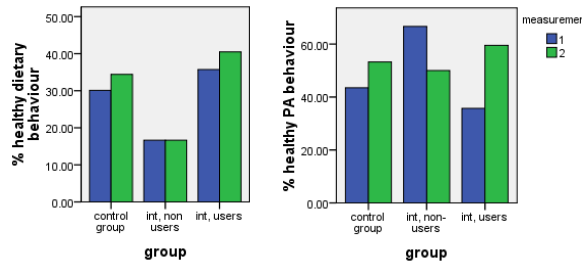

Figure 2 –Healthy dietary and PA behaviour

Insight in behaviour

We can show no significant effect of the intervention on insight in dietary behaviour. However, we did find significant effects on insight in PA behaviour. More users gained a realistic insight in PA behaviour (Z=-2.524; P=0.012). The waiting list group and the intervention non-users did not show a significant change between pre- and post-test. Further analyses of the change in insight of the users showed that the percentage of over-estimators dropped (50.0% pre-test and 23.8% post-test) while the percentage of respondents with a realistic insight increased with the same amount (47.6% and 73.8%). There was no change in percentage of under-estimators.

Conclusion and future work

Conclusions on usage and users

Only little more than half of the participants who received access to the HWA actually used the application. This finding is not unique for this study [see among others: 5,9,19] and stresses an important aspect of web-based interventions. Ostensibly, there is a barrier that prevents almost half of the participants in the intervention group to make use of a web-based intervention to change dietary and PA behaviour. This research sheds some light on the factors that might influence this

Table 2 – Pre- and post-test scores on outcome variables

Variable	Control		Intervention, non-users		Intervention, users		Total	
	Pre-test	Post-test	Pre-test	Post-test	Pre-test	Post-test	Pre-test	Post-test
Diet (mean)	59.1*	60.6	54.7	57.0	60.5	61.7	59.1**	60.6

* Significant difference between pre- and post-test score at the 0.05 level

** Significant difference between pre- and post-test score at the 0.01 level

barrier. First, it is important to notice that knowledge of healthy diet and healthy PA, attitude towards healthy behaviour and self-efficacy to perform healthy behaviour do not seem to have any influence on the choice to use or do not use the application. Significant differences between users and non-users were found on age, dietary behaviour and insight in dietary behaviour. The finding that the users are older, might seem counterintuitive, but it concurs with recent findings on the motivation to use e-consultation [20], which states that older people are more motivated to use this form of eHealth than younger people. The difference on dietary behaviour shows that the people who need the intervention least are most likely to use the application. These users might not feel they need it least, considering they are more inclined to underestimate their behaviour and therefore feel they should improve substantially to achieve healthy behaviour. The opposite might be true for the non-users. Although objectively they might have a greater need for behaviour change, they are more inclined to overestimate their behaviour, therefore they feel the HWA is of little use to them.

Apart from many potential users who refrain from using the HWA, we saw that the HWA is not used regularly. More than half of the users have used it only once. This might be explained by satisfaction scores which fall in the neutral category. If this is the main reason though, we would expect regular users to express higher satisfaction than occasional users. This, however, cannot be concluded from the data. An alternative explanation might be found in the reasons for use. As shown in Table 1, the most important reason for wanting to use the HWA is to gain insight in one's own behaviour. It might be that this goal is reached after using the HWA once. Participants who feel that their goal is reached, might not need to use the HWA again.

Effects of the intervention

Both the waiting list group and the intervention group show significant improvement on behaviour and subjective assessment of behaviour. Participating in a study on these behaviours in itself may provide some motivation to change behaviour by increasing awareness of current and desired behaviour. In this study we found no significant decrease in mean BMI. This indicates that participating in this study did not lead to weight loss. Although 38.7% of participants do want to lose weight (reasons for use, Table 1), this is not a goal central to the application. Therefore we do not feel that this result exhibits a negative effect of the intervention or study. Interestingly, variables known for their predictive value in behaviour change (knowledge, attitude, self-efficacy) cannot explain differences in behaviour in this study. Participants score very positive on these variables, but they remain stable. It appears that other factors might be of more importance in changing behaviours that are not in urgent need for change, as is the case in a preventive intervention as the HWA where people are more or less healthy and want to become healthier.

We have shown that the intervention has a positive effect on PA behaviour. On dietary behaviour this effect cannot be replicated. This might be due to the fact that users show healthier dietary behaviour at pre-test. This group is less likely to score much higher due to a ceiling effect. The results on insight in behaviour show that the intervention has a positive effect on insight in PA behaviour. Over-estimators who used the application are more likely to gain a realistic insight in their PA behaviour than over-estimators who did not use the HWA (intervention non-users and waiting list group). It seems that the HWA is particularly useful for these over-estimators, although we showed that they are less likely to use the HWA. This contrast poses a challenge to the implementation of the HWA: How to reach the people for whom the HWA is most useful? Returning to the research questions stated in the introduction we can say that:

- Using the HWA leads to improvement in PA behaviour and insight in PA behaviour. All participants, regardless of randomized group, show improvement in healthy behaviour and subjective assessment of healthy behaviour.
- People who are older, score higher on dietary behaviour and under-estimate their dietary behaviour are more likely to use the HWA.

Limitations

A major limitation for this research is that we measure effects for a limited group. Only half of the participants with access to the HWA have used it. We have shown that the intervention has positive effects on these people. But, to increase the efficiency of the HWA it is important to get more people to use the application. Furthermore, it might be that the effects are more pronounced for frequent users. This proposition cannot be proven by this research due to a small group of frequent users, but it holds face value and is supported by other studies in similar fields [21,22]. Therefore a major question for both science and practice is how to get people to keep using applications. A second limitation is the use of self-reported behaviours. Although we used questionnaires from literature, as always, there is a chance of biased results due to self-reported behaviour. Another limitation is related to the participants in this study. Most respondents were female and higher educated. Various studies report overrepresentation of this group [5,23], nevertheless, the question remains whether these results can be generalized to the broader target population of the HWA.

Future work

As mentioned in the previous paragraphs, usage is a major issue in research into the effects of eHealth applications. No matter how effective an application is, when there are few users the effects will only hold for a limited group of people. More research is needed into transforming potential users into actual users and into keeping users engaged with the application and thereby stimulating them to keep using the intervention. Attention should be paid to how technology can motivate users that are willing to change their behaviour. A framework which might be useful is provided by Fogg [24], who states that technology can stimulate the performance of a target behaviour by increasing motivators (pleasure, hope, social acceptance), by simplifying the target behaviour, and by providing triggers to perform the behaviour. Examples are found in serious gaming (pleasure as motivator), automating the collection

of data for monitoring (simplifying) and using mobile text messaging as reminders (trigger). By investigating different methods for motivating a target group to become active users, a large leap in efficiency of eHealth applications can be made.

Abstract

This paper presents an online prospective study investigating whether the strength of social feedback, i.e. the proportion of persons who concur or do not concur with one's own answer to a question, influences the way one answers health-related questions. Two hundred and twenty-seven undergraduate students were recruited to use an online search engine to answer six health-related questions. Subjects recorded their pre- and post-search answers to each question and their level of confidence in these answers. After answering each question post-search, subjects were presented with a summary of post-search answers provided by previous subjects and were asked to answer the question again. There was a statistically significant relationship between the absolute number of others with a different answer (the crowd's opinion volume) and the likelihood of an individual changing an answer ($P < .0001$). Subjects' likelihood of changing answer increased as the percentage of others with a different answer (the crowd's opinion density) increased ($P = 0.047$). Overall, 98.3% of subjects did not change their answer when it concurred with the majority (i.e. >50%) of subjects. When subjects had a post-search answer that did not concur with the majority, they were 24% more likely to change answer than those with answers that concurred ($P < .0001$). This study provides empirical evidence that strength of social feedback influences the way healthcare consumers answer health-related questions.

Introduction

Studies reported that people are one of the important sources of information that influences one's actions when confronted with a health-related matter [1-6]. One example is Berkman and Glass's model, which illustrated five ways that social relationships can influence health, such as social influence, social engagement and attachment, access to resources via social ties, social exposure and social support [7].

Social influence refers to how the presence, actions or expectations of others influence the way one behaves [8]. Demonstrated by over eighty years of experimental research, previous studies have examined different classes of social influence, including allelomimetic behaviour, behavioural contagion, conformity, compliance, group pressure, imitation, normative influence, observational learning, social facilitation, suggestion, and vicarious conditioning [8]. In the context of health, the norms of what is considered an acceptable health-related behaviour is often defined by others around you (e.g. smoking), or the controls others impose to achieve adherence (e.g. medication regimens).

With the role of the Internet as a social network, typified by growing interest in sites like Wikipedia, Facebook, and YouTube, more consumers are seeking health-related information and advice from online peer networks. Few studies have evaluated the health impact of social influences that is possible through such websites [9]. Our previous research shows that when consumers search for online information, they experience cognitive biases that influence their health decisions [10] and that such biases are difficult to remove [11]. In particular, pre-existing beliefs are likely to make individuals discount information that is correct [12], where those who lack confidence are 28.5% more likely to change their decision after receiving social feedback online [13].

The aim of this research is to examine whether strength of social feedback, i.e. the proportion of persons who concur or do not concur with one's answer to a question, influences the way one answers health-related questions. We use two measures *opinion volume* (the absolute number of people expressing a view) and *opinion density* (the relative proportion of a group holding a view) to assess the impact of social feedback on consumer health decisions in this study.

Methods

A convenience sample of 227 undergraduate students was recruited from the University of New South Wales (UNSW) to use an online search engine developed at UNSW to answer six consumer health questions. Subjects with Internet access who had previously used an online search engine were recruited by announcements via student email lists, posters, leaflets, weekly student magazines, and a UNSW research news website. The search engine retrieved documents from tested

resources known to have high relevance in answering health-related questions [14], namely PubMed [15], MedlinePlus [16], and HealthInsite [17].

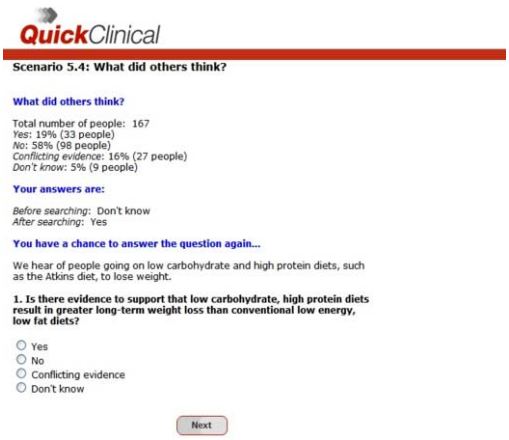

Figure 1- Screen capture of feedback provided to subjects after answering a question post-search

Study protocol

A pre/post protocol was used in this study. Subjects were advised to spend about 10 minutes for each question and to use only the provided search system to answer the questions. To prevent subjects from visiting external websites during the experiment, the navigation bar on the Web browser was hidden once the subject logged on to the study website. Upon completion of the study, subjects were entered into a draw for one of 100 cinema tickets. Ethics approval was obtained from the Human Research Ethics Advisory Panel at UNSW.

Subjects recorded their pre- and post-search answers to each question and their confidence in these answers. After answering each question post-search, subjects were presented with a summary of the post-search answers provided by previous subjects and were asked to answer the question again (Figure 1).

Scenario questions

The consumer health questions and the expected correct answers are shown in Table 1. Each subject was presented with 6 questions, selected at random from the set of 8. There were 4 possible answers to each question: "yes," "no," "conflicting evidence," and "don't know." The questions varied in difficulty and topic in order to cover a spectrum of health care consumer topics. They were developed in consultation with a general practitioner and two academics from the School of Public Health and Community Medicine at UNSW.

Agreement was reached on the "correct" answer and the location of the best evidence sources for each question. A pilot test with 3 members of the general public was used to assess the questions for interest and readability. Two additional pilots, each with 5 subjects, were conducted to confirm that it was possible to locate documentary evidence required to answer the questions correctly.

Table 1- Case scenarios and questions presented to subjects

Scenario question	Correct answer
We hear of people going on low carbohydrate and high protein diets, such as the Atkins diet, to lose weight. Is there evidence to support that low carbohydrate, high protein diets result in greater long-term weight loss than conventional low energy, low fat diets?	No
You can catch infectious diseases such as the flu from inhaling the air into which others have sneezed or coughed, sharing a straw or eating off someone else's fork. The reason is because certain germs reside in saliva, as well as in other bodily fluids. Hepatitis B is an infectious disease. Can you catch Hepatitis B from kissing on the cheek?	No
After having a few alcoholic drinks, we depend on our liver to reduce the Blood Alcohol Concentration (BAC). Drinking coffee, eating, vomiting, sleeping or having a shower will not help reduce your BAC. Are there different recommendations regarding safe alcohol consumption for males and females?	Yes
Sudden infant death syndrome (SIDS), also known as "cot death," is the unexpected death of a baby where there is no apparent cause of death. Studies have shown that sleeping on the stomach increases a baby's risk of SIDS. Is there an increased risk of a baby dying from SIDS if the mother smokes during pregnancy?	Yes
Breast cancer is one of the most common types of cancer found in women. Is there an increased chance of developing breast cancer for women who have a family history of breast cancer?	Yes
Men are encouraged by our culture to be tough. Unfortunately, many men tend to think that asking for help is a sign of weakness. In Australia, do more men die by committing suicide than women?	Yes
Many people use home therapies when they are sick or to keep healthy. Examples of home therapies include drinking chicken soup when sick, drinking milk before bed for a better night's sleep, and taking vitamin C to prevent the common cold. Is there evidence to support the taking of vitamin C supplements to help prevent the common cold?	No
We know that we can catch AIDS from bodily fluids, such as from needle sharing, having unprotected sex, and breast-feeding. We also know that some diseases can be transmitted by mosquito bites. Is it likely that we can get AIDS from a mosquito bite?	No

Table 2- Comparison of changes in answer between subjects who concurred vs. did not concur with the majority (N = 920)

Concurred with >50% of subjects?	Changed answer	Did not change answer
Yes (n=749)	13 (1.7%)	736 (98.3%)
No (n=171)	44 (25.7%)	127 (74.3%)

Results

Of the 1362 potential answers from 227 subjects each answering 6 questions, 338 were excluded from analysis because an answer was not selected, the subject selected "don't know" as the answer, or the subject did not perform a search prior to selecting an answer. The first answer received for each of the 8 scenarios was also excluded, since the first subject to attempt each question could not be given any feedback about other subjects' answers; this left 920 answers for analysis.

Table 2 shows that 98.3% of subjects did not change their answer when it concurred with the majority (>50%) of subjects. Chi-square analysis conducted on data in Table 2 shows that subjects with a post-search answer that did not concur with the majority of subjects were 24% more likely to change their answer than those with answers that concurred (did not concur: 25.7% [95% CI: 19.76-32.77]; concurred: 1.7%, [95% CI: 1.02-2.95]; $\chi^2 = 133.824$, $df = 1$, $P < .0001$).

Subjects were more likely to change their answer when a greater *percentage* of subjects did not concur with their answer – the opinion density (Figure 2). Subjects were also more likely to change their answer when a greater absolute *number* of subjects did not concur with their answer – the opinion volume (Figure 3). There was a statistically significant relationship between the *number* of subjects with a different answer and the likelihood of one changing an answer ($P < .0001$, two-sided Fisher's exact test, Table 3). Chi-square analysis conducted on data in Table 4 showed that amongst subjects whose answer differed to that of >60% of subjects, their likelihood of changing answer *increased* as the percentage of subjects with a different answer increased ($\chi^2=6.10$, $df = 2$, $P = 0.047$).

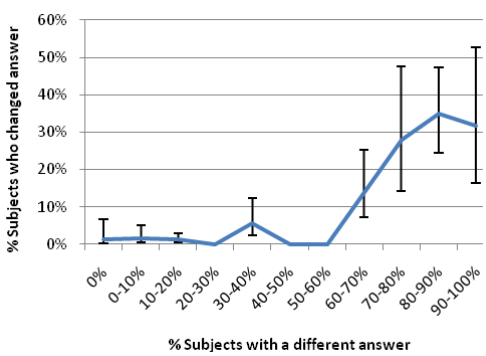

Figure 2- Opinion density effects
(Note: 0-10% means >0% and ≤10%)

Table 3- Comparison of changes in answer amongst subjects whose answer differed to other subjects (N = 920).

No. of subjects with a different answer	Changed answer	Did not change answer
<3 (n=229)	2 (0.9%)	227 (99.1%)
3–9 (n=235)	6 (2.6%)	229 (97.4%)
10–15 (n=225)	6 (2.7%)	219 (97.3%)
>15 (n=231)	43 (18.6%)	188 (81.4%)

Discussion

This study provides empirical evidence that healthcare consumers are more likely to change their answer when a greater number of others do not concur with their answer. It also shows that consumers are more likely to change their answer when their answer is not supported by the majority of consumers. Further, the likelihood of one changing an answer increases as the percentage of subjects not concurring with one's answer increases.

From an empirical perspective, few to no studies have studied the impact of majority influences on how consumers make health decisions. Our previous research showed for the first time that online social interventions can lead consumers to make unsafe decisions about their health. Consumers who are least confident in their decisions are most likely to be swayed by social feedback into making incorrect decisions: those who lack confidence in their answer to a question have been shown to be 28.5% more likely to change their decision after receiving social feedback online [13].

From a theoretical perspective, research on how the majority/minority influences the way individuals process information and alter their attitudes may offer explanations for our findings. One of the earliest and most influential work in this area, Moscovici's *conversion theory* [18-19], proposes that when information is received from the majority, individuals conform to the majority and do not scrutinise the information because they concentrate their attention on "... what others say, so as to fit in with their opinions or judgements" [18]. Whereas, when information is received from the minority, individuals may interpret the information more closely but not as likely to agree with it openly because they fear of being associated with the minority in the public.

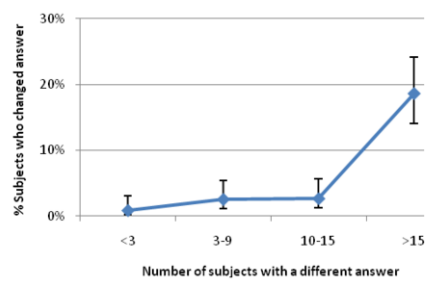

Figure 3- Opinion volume effects

Table 4- Comparison of changes in answer amongst subjects whose answer differed to that of >60% of subjects (N = 167).

% of subjects with a different answer	Changed answer	Did not change answer
60–70% (n=57)	8 (14.0%)	49 (86.0%)
70–80% (n=25)	7 (28.0%)	18 (72.0%)
>80% (n=85)	29 (34.1%)	56 (65.9%)

Note: 60–70% means >60% and ≤70%

Another piece of prominent work in this area, *objective consensus* approach [20], offers several possibilities on why individuals are more likely to systematically process information received from the majority than from the minority. One possibility is that individuals believe their attitudes are similar to those of the majority and are more likely to agree with the majority than the minority [21]. Another possibility is that individuals believe it is more important to process information received from the majority because attitudes held by a majority are more likely to become adopted than those held by a minority [22]. A further possibility is that individuals assume that the majority views reflect reality because "several pairs of eyes are better than one" [20].

Conclusion

The Internet has delivered a glut of information, much of it neither timely nor correct, thus increasing the chances that consumers using the Internet to obtain health information may make the wrong health decision, or experience anxiety about what to do [23]. As consumers play an increasingly active role in managing their health, it is important not to underestimate the extent to which online peer networks can influence the way people manage their healthcare. While the rise of the Social and Semantic Web has facilitated ready access to information about the masses and aggregated behaviours [24], the quality or correctness of aggregated behaviours is often measured by popularity, which does not necessarily relate to accuracy. More investigation should be undertaken to examine whether aggregated behaviours made possible via the Web is a new form of social influence that impacts significantly on consumers' health decision-making.

Acknowledgements

The authors would like to thank Dr. David Thomas and Dr. Ilse Blignault for their assistance in subject recruitment and the development of the health care consumer case scenarios. This research was supported by the Australian Research Council SPIRT grant and APAI scholarship C00107730. The search engine used in the study was developed with support from NHMRC project grant 300435 and the NHMRC development grant 300591. None of the funding sources had any role in the design and conduct of the study; the collection, management, analysis, and interpretation of the data; or the preparation, review, or approval of the manuscript.

Abstract

The arrival of the Internet contributes to the growth of new areas for patient empowerment. In the presence of a challenge such as this, we nevertheless note that the adequacy and characteristics of the web strategies of healthcare providers have, up to the present, not been subjected to thoroughgoing critical analysis. The aim of this paper is to: (a) provide an analysis of the key factors of an efficient web strategy for healthcare organizations with regard to the issue of patient empowerment (b) build a concise indicator for measuring the degree of empowerment potential of healthcare providers' web sites (Patient Web Empowerment Index –PWEI-). PWEI was calculated in order to assess the web sites of 340 Italian National Health Service healthcare organizations, the aim being the appraisal of the current degree of maturity of their web strategies in relation to potentials for an effective increase in patient empowerment

Keyword:

Patient advocacy, Patient participation, Health promotion, Internet, Medical records, Telemedicine, Social marketing, Italy

Introduction

The arrival of the Internet has deeply impacted relations in terms of the exchange of goods and services in innumerable contexts. We may note that the major impacts of these transformations on relations between 'suppliers' and 'customers' consist in: (a) low-cost availability (or availability even free of charge) to the customer of considerable amounts of information useful for purchasing decision-making; (b) a consequent increase in the degree of transparency of markets; (c) a significant enhancement of the empowerment of citizens/customers in many real life situations and in relations with various (public or private) suppliers. Nowadays, citizens are aware of this historic change and are bearers of a growing demand for the adoption of web services, also within contexts such as healthcare, in which, traditionally, exchanges of information between patient and care provider are significantly 'asymmetric'and formal. Patient empowerment, markedly tied in with the spread of the Internet and of technological resources as a part of our day-to-day lives (in which the Internet is now 'embedded'), represents one of the major challenges healthcare systems face today. Statistical data regarding the use of the leading search engines indicate that questions concerning "health" are decidedly among the most frequently occurring. More broadly speaking, patients are nowadays the bearers also of new demands or desiderata, which we may summarise as follows: (a) access to authoritative, customized and immediately usable health information; (b) greater control over their own personal conditions of health, through personal management of pertaining data, and over the various diagnostic and therapeutic options available; (c) direct and informal relationships with healthcare structures and professionals, also via non-traditional channels; (d) role as 'active player' within the network, also by sharing ones health problems with others and seeking out information on the experiences of others faced with these same problems (web 2.0 rules, the basis of social networks, has considerably amplified this latter development).

In equal measure, in the scientific literature and strategic decision-making processes in the field of healthcare provision systems, the concept of "patient empowerment" therefore constitutes an increasingly significant variable, which is the focus of interest and debate among academics and policy makers alike [1-3]. Within the field of healthcare provision, the concept of empowerment has been adopted on various levels [4]: on the macro level, analysis takes place of the relationship between health and power. A number of studies suggest that empowered people are healthier than non-empowered people; lack of power is therefore a disease risk factor (dependent upon structural factors) [5]. On the micro or individual level, the concept of empowerment has been used to define a particular type of patient. It is here that we arrive at the notion of patient empowerment:

> *"Patients are empowered when they have the knowledge, skills, attitudes and self-awareness necessary to influence their own behaviour and that of others (...) to improve the quality of their lives [6]."*

In the presence of a challenge such as this, we nevertheless note that the adequacy and characteristics of the web strategies

of healthcare providers have, up to the present, not been subjected to thoroughgoing critical analysis. The aim of this paper is to: (a) provide an analysis of the key factors of an efficient web strategy for healthcare organizations with regard to the issue of patient empowerment (b) build a concise indicator for measuring the degree of empowerment potential of healthcare providers' web sites (c) measure the degree of patient web empowerment within the Italian National Health Service (INHS).

Methods

The research project described here aims to engage in a more in-depth study of, and to elaborate upon, the issue of patient empowerment within the context of the introduction of information and communication technologies (ICT). A study has been conducted of the healthcare applications of these technologies, classified according to their impact on the two key dimensions of patient empowerment: information held by the patient and control on the part of the patient with respect to his/her health needs. The baseline research hypothesis is that the information and services provided by Health providers via the web are capable of enhancing patient empowerment regarding both the above mentioned dimensions.

The basic question this research addresses may be summed up as follows: *"To what extent are the web strategies of IHNS organizations aimed at increasing patient empowerment?"*

The various typologies of web information and services were used to develop a succinct indicator by means of which ratings could be given for the web sites of Italian Local Healthcare Units (LHU) and Hospital Trusts (HT). This indicator, termed Patient Web Empowerment Index (PWEI), is the result of aggregation and weighting of 8 sub-indicators, each of which is calculated on the basis of the presence of certain elements characterising the structure of the web site considered[1].

During the period April-June 2009, the indicator was used to assess the web sites of the entire universe of public (and private contracted) INHS healthcare organizations (340 LHUs' and HTs' sites were benchmarked), the aim being the assessments of the current state of maturity of their web strategy in relation to potentials for an increase in patient empowerment.

Analysis and rating of sites were based on two fundamental criteria: (a) the immediacy in finding information or services while navigating the site ("hidden" services were not considered if time-consuming procedures were necessary in order to find them); (b) the official and systematic (as opposed to sporadic or "test only") presence of the information or services in the examined web sites.

Construction of the *PWEI* indicator

PWEI, as pointed out above, is a multidimensional indicator, composed of a series of sub-indicators the objectives of which are measurement of the various aspects of patient empowerment via the web. The typologies of information and services that users can find on the sites of Italian health organizations, in fact, vary greatly. Thus, the capacities of these health organizations to contribute to user empowerment also vary – empowerment ranging from access to knowledge, to control of data concerning ones personal conditions of health via the electronic medical record and telemedicine.

Figure 1 illustrates how the main *PWEI* sub-indicators are linked to the main ambits of influence of ICT on the web sites of LHU and HT and the impact of these ambits on the two elements defining patient empowerment: information and control.

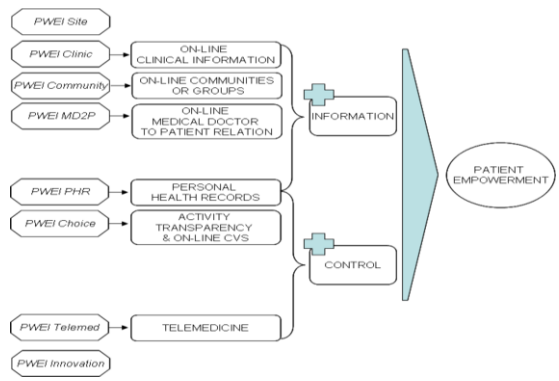

Figure 1 - The main influences of ICT on patient empowerment

The first element making up the overall index of patient empowerment has been termed ***PWEI Site*** **(P1)**. It relates to certain structural characteristics of the site which enable user-friendly navigation and which, above all, respond efficiently to the primary information needs of the patient. Assessment was conducted of a number of these characteristics: accessibility (e.g. the option of graphics changes, including font size, for patients with eyesight problems, or to facilitate handheld computer or mobile phone site access) and immediate usability of the content and services provided by the examined healthcare provider. Site structure was examined, including rating of sites enabling the life events model for navigation (i.e. navigation starting out from events which may characterise the life, in health terms, of the patient, such as "giving birth", "growing" or "life as a senior citizen"), or which provide clear segmentation of patients by cluster (the elderly, women, children, foreigners etc.). Menus constructed according to these approaches may aid consultation by patients presenting specific problems, who thus receive immediate answers targeting their specific needs. Lastly, an exhaustive description of the health organizations and their departments may aid the patients in that the description can be used as a map for orientation among the services provided: clear presentation of the organisational structure of the health unit was therefore also assessed.

[1] During the stage of quantitative determination, the value 1 was ascribed to the presence of the service or of the information considered, value 0 to absence, and value 0.5 to incompletely structured presence.

The second component of the indicator consists in the clinical information that may be obtained by patients from the site. To construct sub-indicator ***PWEI Clinic (P2)***, various elements relative to health information present on the site were considered, ranging from simple leaflets or fact files to tests for assessment of the clinical risks of individuals or information for self-diagnosis. Investigation was conducted of the presence of: i) leaflets or fact files on specific pathological states; ii) files dealing with prevention and for promoting correct lifestyles; iii) files to aid understanding of laboratory examinations; iv) healthcare provider magazines or newsletters with information regarding health and healthcare issues; v) back-up with guidance for self-diagnosis; vi) questionnaires and clinical risk assessment tests. Use of each of the first four elements can generally be enabled by file downloading or – in rare instances – by video, links to internal resources (web pages maintained by professionals from the health unit) or links to external resources (the resources of the Health Ministry, the sites of Regional government authorities or regional health agencies, on-line libraries).

The third component of the indicator is termed ***PWEI Community (P3)***. This sub-indicator assesses web site presence of on-line communities or of groups which ensure clinical back-up in the form of information, psychological support or a service consisting in accompanying patients with special health problems. The following entities were noted: i) institutional communities: counselling; on-line support centres (e.g. stop-smoking, dietary health problems, etc.); health organization linked voluntary associations; ii) bookmarks for Internet support group resources, i.e. direct links to medical sites or sites run by voluntary players or by patients; iii) lists of, and references to, non-web community and support group resources (generally, address directory mode).

A further indicator factor – contributing to significant enhancement of the quality and quantity of clinical information available to users – consists in direct on-line medical doctor-patient communication (***PWEI MD2P – Medical Doctor To Patient – P4***): patients can directly contact professionals for health information or advice. In this context, the prospect of adoption of a multi-channel approach on the part of health organizations was also considered (telephony or digital terrestrial television communication resources, alongside the Internet). Thus, the systematic presence of the following elements was assessed: i) telephone line for counselling or general healthcare orientation purposes, ii) telephone line for health counselling on specific issues (e.g. influenza, contraception, AIDS, etc.), iii) use of personal email communication on the part of the organisation's medical doctors, iv) moderated institutional forums for communication among patients, v) blogs, forums or live sessions for communication between patients and medical doctors, vi) FAQ service on health issues providing medical doctors' answers to users' questions.

A further key aspect considered for an assessment of empowerment consists in access to ones own ***Personal Health Record (PHR – P5)***, generally understood as an electronic format record with information on the health conditions of the individual, alongside a record providing the full medical history of the person in question, directly accessible via web. *PHR* is therefore an important instrument in terms both of information and control of ones own personal health data. Sub-indicator *PWEI PHR* analyses openings for examining and downloading ones own electronic format record directly from the health unit's site or by other means (e.g. via electronic card or access on the part of the patient's general practitioner or specialist).

The expectations of many users have grown, and these users display greater awareness of the importance of selecting professionals and the most appropriate structure (safety, specialisation, available technologies and methods, etc.) for healthcare provision and optimal responses to their health problems.

This aspect was processed by means of a further component of the index, i.e. ***PWEI Choice (P6)***. This sub-indicator accounts for a number of the most important elements which, if present on the site, may provide patients with orientation in selecting the most appropriate health unit and professionals for the required service. These elements, in any case, are auspicious in terms of transparency of health unit during dealings with users, namely by provision of user-friendly access to: i) medical doctors' curriculum vitae data, ii) information on the typology and quantity of treated cases by pathological condition, iii) waiting lists for diagnostic services, specialist examinations and emergency room admissions.

The need to meet increasingly complex demands brings with it the need to re-configure the manners in which certain health services are provided, this latter aim receiving a significant stimulus from progress in the ICT field. In this context we note the potentials of telemedicine, which generally enables virtual mode clinical diagnosis without physical contact between patient and medical doctor. For the purposes of analysis, a search was made for unequivocal provision of the following services on the sites of health units: i) specialist tele-counselling, ii) telehomecare iii) emergency telecare. Assessments relative to these elements were pooled in sub-indicator ***PWEI Telemed (P7)***. The availability of services provided by telemedicine system enables greater control by the user of personal conditions of health.

Lastly – for individual cases – the presence on sites of certain ancillary ICT-based services was surveyed, such as webcam or photo albums for newborns (provided by maternity departments or by intensive treatment departments). These innovations were translated into the last of the index elements: ***PWEI Innovation (P8)***, gauging the presence of particular innovations (including innovations which are exceptional in nature and which go beyond the impacts, in terms of information and control, investigated during the research under discussion here).

Each sub-indicator was weighted according to its significance for the enhancement of patient empowerment[2]; weights were determined on the basis of scientific literature on patient empowerment and then validated with the involvement of a pool

[2] A sensitivity analysys of the adopted weights is available upon request

of experts. The total value is reached by means of equation (1). The maximum theoretical value of the weighted PWEI is 10.

PWEI = 0,5 P1+ 2 P2 + 0,5 P3+ 1.5 P4 + 2 P5 + 2 P6 + 1 P7 + 0.5 P8 **(1)**

Results

From analysis of the single *Patient Web Empowerment Index* indicators we learn that, as yet, few health organizations have developed web-based strategies oriented toward information and user control of clinical data. Although, nationally speaking, the presence of best practices was noted (above all, in Lombardy and Emilia Romagna regions), it was observed that none of the local health units surveyed had reached an overall PWEI rating approaching the maximum theoretical value of 10.

The overall *PWEI* results can be assessed by geographic area (Table 1). Here, the health units of Northeastern and Northwestern Italy rated higher than the national average. The data reveal a nationwide gap situation with regard to patient empowerment via web sites. While Northern Italy's average *PWEI* values were not particularly high, the area does seem to be gradually coming round to the idea of paying more attention to web strategies targeting the users of its health units. The health units of the Regions of Central and Southern Italy still display an inability to implement the openings provided by the web for responding to patient needs.

Table 1 – Average PWEI by regional cluster (min 0- max 10)

	PWEI by regional cluster
Northwestern Italy	2.20
Northeastern Italy	1.85
Italy	**1.50**
Central Italy	1.07
Southern Italy	0.98
Islands	0.78

Particularly worthy of note is the prospect of *PWEI* sub-indicators analysis. The average national values for *PWEI* sub-indicators are listed in Table 2 (on a 0-10 scale).

Table 2 – National average values for each PWEI sub-indicator (min 0- max 10)

	Average Px value
PWEI Site (P1)	3.55
PWEI Clinic (P2)	1.10
PWEI Community (P3)	2.13
PWEI MD2P (P4)	0.94
PWEI PHR (P5)	2.79
PWEI Choice (P6)	0.32
PWEI Telemed (P7)	1.06
PWEI Innovation (P8)	0.46

The data indicate the greater significance of the *PWEI Site*, *PWEI Community* and *PWEI PHR* sub-indicators. For *PWEI Site*, the value is directly ascribable to the existence at least of an institutional web site. For *PWEI Community* and *PWEI PHR*, the result is owing to the positive outcomes noted in a number of the major health units.

Discussion

The analysis offered a number of interesting results regarding each of the surveyed ambits and a number of best practices, where these could be found.

With regard to the ***PWEI Site*** component, research revealed that very few health organizations had enabled a system for web site use of information based on a life event approach. Other health providers selected visitor-type clusters (e.g. the elderly, special-needs patients, foreigners, etc.) as a means of orienting information users. While taken up by a greater number of health organizations (compared to the life event system), this latter option remains infrequent within the entire surveyed sample. Indeed, this was the choice made by most health organizations in Emilia Romagna Region and by a considerable number of organizations in Lombardia Region. In the other Regions, however, this type of segmentation of visitors was sporadic, the menus bring based instead on the organisational structure of the concern (e.g. districts, departments, hospitals etc.).

Analysis of P**WEI *Clinic*** elements revealed that there are practically no guided support resources for self-diagnosis or assessment of personal clinical risks (the two exceptions regard diagnosis of cardiovascular and melanoma risks). The LHU generally provide downloadable leaflets dealing with prevention, above all for tumour screening and for promoting healthful lifestyles. Information files on specific pathological states are more frequently to be found on the sites of HT than on those of LHU concerns.

Turning to communities aspects (***PWEI Community***), only a few health organizations host institutional support groups (in most cases, voluntary associations for specific patient types). Sites hosting bookmarks or lists of pertaining associations are more frequently found. This information was systematically included in the sites of the health organizations of specific regions.

In terms of medical doctor-patient relations (***PWEI MD2P***), few health organizations have, as yet, made provisions for an interactive approach to exchanges between the two players. Indeed, there are few telephone lines for patient orientation on health concerns, both with regard to general services and specific areas of specialisation. On their sites, the health units of Emilia Romagna refer to a dedicated AIDS telephone line (*Helpaids*): the project was actually started up by the Regional authority, and not by LHU. Generally speaking, medical doctors' personal email addresses are not hosted by sites, with some exceptions (while cases are to be found, this service does not generally regard all medical doctors of the organisation). Only on some sites are user-accessible forums and blogs to be

found. Managed by counselling centres, they target adolescents and women. Solutions enabling medical doctors to respond to user questions via the FAQ function are slightly more frequently to be found.

For *Personal Health Record* (***PWEI PHR***), we must distinguish between two differing operational ambits: i) single health organizations which independently decide to acquire systems for counselling and for patient downloads of electronic format health files; ii) *PHR* systems finalised within the ambit of regional projects. In the former case, there are, as yet, few health organizations which have made provisions for such instruments. Only in the Lombardia and Emilia Romagna regions have solutions been devised for clinical data management on a regional level (the CRS-SISS[3] project for Lombardia and the SOLE[4] project for Emilia Romagna). These regional projects were considered when assessing the sites for the health organizations of these two regions, and the presence of *PHR* was duly taken note of, although at present the projects have not been fully implemented in terms of the prospect of direct *PHR* use on the part of patients [7] [8].

Performance for telemedicine (***PWEI Telemed***) among health units is still unimpressive. A number of LHU especially in the Veneto, Emilia Romagna and Toscana regions, do have pilot projects, ranging from emergency telecare for infarcted patients to telehomecare for the elderly.

With regard to ***PWEI Choice***, we note that, with the exception of certain organizations, the sites do not systematically include curriculum vitae data for their professionals and there is practically no information at all on case-mix treated by health organizations or professionals. Managers' CV publication is foreseen by law at a national level as an admnistrative pro-transparency measure; real-time waiting lists data are available only on approximately fifty sites (at times, data are provided only for specific services).

Conclusions

A number of preliminary conclusions may be reached on the basis of this study. Three general points may be considered:

- health units' awareness of the potentials of web instruments for curbing 'asymmetric information' situations (a typical characteristic of relations between medical doctor and patient) is only partial. Indeed, few organised resources have been made available such as provide solutions capable of responding to a broad range of health needs displayed by the citizenry;
- we find considerable resistance to the idea of using the web as a means of truly and significantly enhancing transparency, this aim being frustrated to a considerable extent. This situation is evident for all areas and all 'critical' services, i.e. "real views" (of waiting lists for services) or online CVs of professionals. While we are aware that the degree of cultural resistance to such innovations is significant, we believe that this ambit may represent a natural line of development of some interest for web strategies;
- the web strategies of health organizations basically reflect a state of immaturity. The strategies still display a tendency to modulate their approach with the accent all too frequently placed on the structures and responsibilities of the organisation itself, rather than on the needs and demands of citizens-patients. While site design seems to be well executed from the graphics angle and the information content is updated in a satisfactory manner, the logic behind design is still based on considerations regarding the concrete organisation of the structure. Patients may well not be familiar with such organisational aspects. By adopting this approach, transparency may be impeded with respect to specific needs.

Overcoming these three highly significant limits may turn out to be a prerequisite for concrete development of the provision of "healthcare 2.0" – a concept for innovation which healthcare systems are beginning to discuss.

[3] The CRS-SISS (Regional electronic card for access to health data and public services) project of the Lombardia regional authority aims to plan, develop and manage the information system enabling telematic links in the region.

[4] The SOLE (Sanità On-line), or on-line health care, project consists in a computer network with links between 3,800 general practitioners and paediatricians and all the medical structures and specialists of the health units of the Emilia Romagna region.

Development and Implementation of an Integrated EHR for Homecare Service: A South American Experience

Jerónimo Aguilera Díaz, Antonio Eduardo Arias, Cintia Mabel Budalich, Sonia Elizabeth Benítez, Gastón López Damián Borbolla, Fernando Plazzotta, Daniel Luna, Fernán González Bernaldo de Quirós

Department of Health Informatics, Hospital Italiano de Buenos Aires

Abstract

This paper describes the development and implementation of a web based electronic health record for the Homecare Service program in the Hospital Italiano de Buenos Aires. It reviews the process of the integration of the new electronic health record to the hospital information system, allowing physicians to access the clinical data repository from their Pc's at home and with the capability of consulting past and present history of the patient health care, order, tests, and referrals with others professionals trough the new Electronic Health Record. We also discuss how workflow processes were changed and improved for the physicians, nurses, and administrative personnel of the Homecare Services and the educational methods used to improve acceptance and adoption of these new technologies. We also briefly describe the validation of physicians and their field work with electronic signatures.

Keywords:

Hospital information systems, Homecare services, Clinical data repository, Electronic signatures.

Introduction

Patient care in the home setting is a complex task. There are ongoing and intricate interactions between patients, medical, and administrative staff. Physicians and health care professionals, such as those in ancillary services, may be impeded in giving prompt care without access to real time clinical data or if they are unable to share knowledge efficiently. Communication can fail and when these elements are not properly coordinated, errors can occur. [1]

Compared with other levels of health care, homecare service involves a substantial flow of information. Delivery of services requires coordination of geographically distributed patients and professionals by central administrative personnel who usually have little access to vital medical workflow decisions.

For the personal that works on homecare services, to have restricted access to some of the right information in real time and in an not optimal format makes it difficult to make the decisions in their work. [2]

Much of the clinical and technical orientation in Home Care Service (HCS) is on telemedicine; previous works described how to improve the care of special patients with specific diseases or how to extend the telehealth to the home.[3, 4].Or even, describe technical support for close care and consistent information flow between different health care providers.[5]

Because Hospital Italiano de Buenos Aires (HIBA) wished to integrate all levels of care in the Hospital Information System (HIS), we decided that HCS should have the same interface as the existing applications. To create and put in place a platform that supports such complex model was not a trivial task: it required a carefully planned design.

The objective of this paper is to describe the experience of the development, integration, and implementation of an Electronic Health Record for HCS into the HIS of the HIBA. Our first planning phase and our first results involved two target populations in HCS, “"Homecare"” and “Follow up care”.

Materials and Methods

The Hospital Italiano de Buenos Aires (HIBA) is a non-profit health care academic center founded in 1853, with over 1,500 physicians and 3,500 employees.[6] HIBA has a network of two hospitals with 750 beds (200 for intensive care), 500 "Homecare" patients under care, and 23 clinics. It has an insurance plan that covers approximately 150,000 people and also coordinates insurance for another 1,500,000 people who are covered by affiliated insurers. Each year over 38,000 inpatients (pediatric and adult) are admitted to its hospitals that are located in Buenos Aires and its suburban area. HIBA has more than 2,200,000 outpatient visits annually from patients from across the country and Latin America.

HIBA, a well-developed teaching hospital, offers both graduate medical education and residency training for 35 medical subspecialties and 34 fellowships programs. There are currently 400 residents and fellows in training.

In 1998 HIBA began the implementation of a Healthcare Information System (HIS) by integrating clinical information with administrative applications that were already in use. This in-house project currently handles all clinical and administrative

health care information from data capture through to analysis. It is now a fully implemented web-based, problem-oriented and patient centered EHR system.[7, 8] The system includes computerized provider order entry (CPOE) which is available to physicians throughout the HIBA network.

Early in 2008 we decided to start the design and in 2009 implementing the EHR into the HCS. We involved staff from admission, physician, billing for the process of design.

HCS Overview

The Homecare Service is different from all other clinical areas at HIBA; geographically HCS provides services over an area of approximately 350 square km (City of Buenos Aires). Has an average count of 350 to 400 admitted patients and is divided into two different areas according to the level of the patient care.

- 80 to 100 are allocated in Follow up care" (FC). Under Follow up care are those patient whose disease is not that acute and needs one physician and nurse visit per month, e.g. follow up to medication for deep venous thrombosis,
- 270 a 300 are allocated in "Homecare" (HC). Under Homecare is denominated for those patients whose disease only needs one home physician or nurse visit per week, e.g. surgical wound infection.

HCS is provided by 61 physicians : 49 internal medicine physicians, 12 physicians from others specialties (Cardiology, Psychiatry, Trauma, General Surgery, Infectious Diseases, Neurology, Palliative Care, Urology) and 4 physician-auditors that coordinate the service. 32 nurses that administer medications, draw blood samples, monitor and provide daily physical care and 6 Administrative personnel that coordinate the ratio patient/physician by location.

The Homecare Service Pre-Implementation

Pre-implementation administrative processes

The admission consists in the classification of patients and the determination of the priority of needs and the scope of treatment: homecare or follow-up care. Most of cases administrative workflow starts with an inpatient being admitted in HIBA. Each patient selected to be admitted to HCS from HIBA was assigned a physician who performed the first evaluation. This evaluation defined the scope of admission into HCS (FC or HC). The admission was done by an administrator by adding patient data to a spreadsheet. Then manually they admitted to the HCS, and added medication and oxygen if it was needed. Once the admission was confirmed in HCS office, the administrator opened another spreadsheet where all physicians were listed and then assigned a physician whose address most closely matched the patient address. Finally the administrator called or sent an e mail to this physician informing of the patient admission and assignment. The same process was followed in nursing.

All information related to the admission was manually added and shared trough a spreadsheet, with the exception of email notification. Another spreadsheet included the number of patients admitted with the personal contact information.

Pre-implementation Clinical workflow

A patient's case history was accessed from the HIBA EHR through a Virtual Private Network (VPN); this also displayed the levels of care that patient had received. If a laboratory or radiology test was requested, the physician needed to call or to send e mail to the administrator for coordination with the nurse. This process had an average delay of 5 days. The laboratory nurse then took the administrator's call and had to update the patient information in the spreadsheets; this increased the possibility of clerical error. Results were seen in the Ambulatory EHR through VPN connection. Also if a patient needed to be readmitted to HIBA because of a complication, the HCS physician was infrequently informed in real time of this re-admission.

Design of the Homecare Services EHR

The design consisted on meetings and analysis of HCS needs based on pre-implementation evaluation on 2008. This initial design was for defining obligatory applications and functionalities of the HCS EHR should have similar to the EHR already running at HIBA so the integration was more equal. In this meeting, personal of the technician service were present too, and the basis of module was developed. Then in a second phase, the 4 physician-auditors of HCS were invited to review the HCS EHR prototype. Few changes where asked, but the most important need was for physician validation, authentication and certification, so electronic signature was adopted as a form of authentification.

Implementation Plan

Training in the use of the Admission Discharge Transfer (ADT) Application

ADT training of full time HCS administrative staff was done one month prior to the implementation. The ADT system for inpatient has been a part of HIBA for more than 8 years. ADT interacts with the EHR for many patient admissions, discharges and transfers. ADT workflow process was modified with patients leaving the HCS "domain" to the HIBA emergency room and either return to HCS or is admitted to HIBA administrative staff from both HCS and other services were informed and trained in order to avoid compromising patient care.

Training in the use of the "Homecare" Service EHR

Training in the use of HCS EHR was given one month prior to implementation. Physicians who were to use the application on a daily basis attended a workshop, and were given face to face instruction. All instruction manuals were provided on HIBA's "virtual campus". A more detailed course was created for newly registered physicians. They were required to take an exam, after which they were given access to the EHR.

The implementation of the Electronic signature

HCS EHR physicians received virtual and face to face instruction on how to install the software and the hardware. All HCS physicians were required to sign a legal agreement that was validated by the legal department of HIBA. This agreement is an informed consent that validates the physician signature on electronic documents; it provides security, privacy, confidentiality and authorship of the information entered on the EHR.

Results

Informatization of the Homecare Services

ADT system functionalities

Once HCS is integrated into ADT system an admission to this service precedes as follows: First the medical team of the HIBA decides to admit the patient to HCS. Second, an email is sent or a call is made to the HCS physician-auditors. Third, when the patient is physically admitted into the HCS system the auditors' physicians call the HIBA medical team to request the HIBA discharge via the EHR.

The administrative inpatient personal of HCS receive an email alarm with the data of the patient to be admitted. They re-check the data with the physician-auditors and then confirm the incoming ADT message. The clerk creates the episode and all the personal data of the patient is loaded automatically from the Master Patient Index. At this point if the patient is not discharge from inpatient episode through the EHR, the clerk has an option that is called "PRE DISCHARGE". This state allows to virtually admitting the patient for 48 hours waiting for the medical team of HIBA discharge. The ADT system interacts with the Geographical Information System (GIS) so the patient address can be located.

The Homecare Service EHR

Access to the Homecare Service Electronic Health Record (HCS EHR)

Because of the geographic distribution of physicians the HCS EHR is through web access. Homecare Services physicians can access to the EHR from any PC with Internet connection. Physicians log into the HIBA web page and then to HCS through an icon on the intranet web page. There though a SSL certification and two servers that make web application between the Data Base and the web. The web app server 1 include web applications without logic and the web app server 2 with the logic. You can only access the Data Base server by IP assigned by web app 2, then Physicians are sheltered from the Data Base web server thought the web app 1 that can not get to the Data base server. Thought this way all data is preserved. Information flows safely and encrypted.

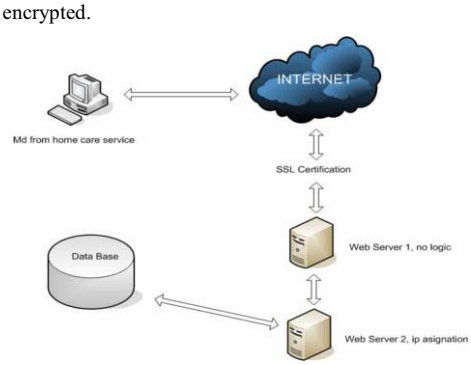

Figure 1- Network & data flow diagram

The Homecare Service Electronic Health Record

The first screen a physician views shows lists of patients, clinical practice guidelines, and a messaging system. This intermediate level default display presents a preferential way of visualization.

Patients' records can be retrieved through a search function. After the physician retrieves the correct patient he/she is presented with a modular, problem oriented and patient centered EHR.

The modules available are:

- Overview: The initial view where all modules are summarized.
- History and Problem lists: This module allows for the visualization of the clinical history. It also provides for the addition of new problems or change in of level of care which had been entered into the Problem Manager by other clinical staff.
- Progress Notes: This is a critical view for physicians. Patient co morbidities and, clinical history is integrated into the record which physicians can easily navigate. The physician can access laboratories results, additional studies, current and historic medications prescribed, and write progress notes (Figure 2)

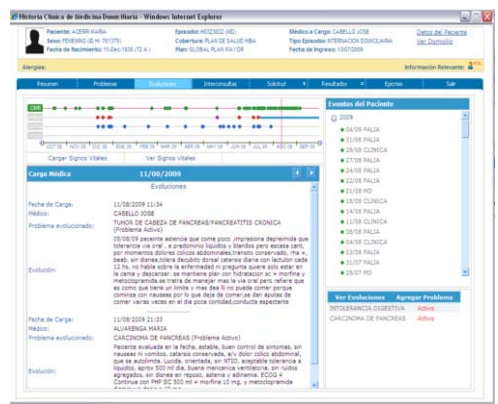

Figure 2- Progress notes module of the "Homecare" Service

- Referrals: The physician can request consults for their patient with any HCS specialist through the EHR. This request automatically generates two e mails -- one to the specialist and the other to administration as an advance notice for billing purposes.
- Clinical or lab studies: the physician can electronically order new studies and lab tests. In addition when if the lab test requires a blood sample to be drawn an email is sent to the nurse where they coordinate the draw example.
- Results: All historic and current studies can be accessed and reviewed. In some instances visualization tools have been created for improved longitudinal result views.

- Episode data: This module enables the physician to close the episode and discharge the patient. The discharge summary includes a principal diagnosis, if necessary a second, comorbilities, and an episode; and with the epicrisis.

Patient discharge of Homecare Service

The finalization of the episode is complete; as said before, by the discharge summary. When it is determined that a patient can be discharged; also to other areas of HCS such as "Follow-up Care" if patient was on "Homecare" and vice versa. When the patient is finally discharged by the physician through the EHR, ADT sends an automated alarm and email to the HCS administrator and they can then finalize the episode.

The more complex situation occurs when the patient experiences an exacerbation of his or her disease(s), is admitted to the ER and needs admission to HIBA for higher level care. When in the emergency room physician admits the patient an ADT automated alarm is sent to the HCS physician and the other to the HCS administrative staff. HCS administration gives the patient a "PRE DISCHARGE" notation in ADT\ which allows the HCS physician 48 hrs to complete the discharge in the electronic medical record of HCS EHR.

Electronic signature

Since authentification is done by electronic signature, a digital photo is taken and printed in a chip card with personal data (private key and certificates), which is given to each physician with an USB card reader to install on their PC or Notebook (Figure 3). A paper instruction manual and a face to face tutorial on electronic signatures were provided. In addition we replicated this information in our"Campus Virtual del HIBA (www.campus.hospitalitaliano.org.ar)"; here they could download the manual and see the instruction at their convenience or for knowledge reinforcement. The documents to sign were the new clinical notes, the discharges and discharge summaries.

Figure 3 - Agreement-Card-USB card reader

Post-Implementation Data Analysis

During the period from January 2009 August 2009, the HCS admitted a total of 10,836 patients, 82% of "Homecare" and 18% of "Follow-up".

There is an average of 26 days of hospitalization for "Homecare" and 38 days for "Follow- Up care".

32 % of the patients admitted on ER where from HCS because of exacerbation of their disease.

The ten most frequently input clinical disease were taken from ICD 9 classification. During the same period, the four most frequent were: Essential hypertension (27%), Dementia (12%), cognitive deficit (11%), Urinary tract infection (8%).

The remainder was further classification of factors influencing health status, infections and diseases of the nervous system and sensory organs, injuries and diseases of the circulatory system, musculoskeletal and connective tissue, and the genitourinary system.

Clinical information captured will enable research, audits to improve care and better clinical management. Improved patient monitoring identifies deficiencies in the process and assists management in the HCS [9].

Workflow can be monitored online and patient's relatives can be better informed. The initial stages were overcome, but one of the critical was the transition from the administrative work in paper to the electronic form. Also to select the proper technology and way of implementation so the work flow is not interrupted.

Other critical task was not to add unnecessary complexity or increase the cognitive effort required for interaction with devices. If information technology is not implemented or not well integrated into the work often result in duplication or suboptimal division of tasks. [10]

The limitations of our work were that we didn't measure any outcome or any test of usability yet. Another limitation of the system that is being developed and nearly implemented, the possibility that nurses can write notes and physician can prescribe the patient's chronic medications.

Conclusion

The design and implementation allowed, personal previously excluded (medical, administrative, and nursery) now included in the Health Information System of the Hospital Italiano. Strikingly improved the staff communication of the HCS with the rest of the Services and between themselves too. Now there is information into Clinical Data Repository and also to manage and audit for future. Now all patients are correctly located in the city with georreference. All clinical notes of physicians are complete and more organized.

Acknowledgments

We thank the physicians, nurses and administrators of the Homecare Service of HIBA.

Abstract

Population ageing needs health-enabling technologies for delivering pervasive health care. Home care plays an import role in pervasive health care. In this paper, we aim to construct a home-centered health information system architecture which can efficiently manage multi sensors, actuators and decision support systems. Open Services Gateway initiative (OSGI) was used for constructing the service oriented architecture. HL 7 Arden Syntax for medical logic module (MLM) was used to describe the medical knowledge; An Arden compiler was used to interpret the MLMs. The Arden compiler was packed in an OSGI bundle. All of the knowledge bases can share the compiler within the OSGI platform. System within the OSGI-based architecture can change their behaviors during runtime. The proposed prototype architecture was deployed in a case study.

Keywords:

Health-enabling technologies, Home care, Information system architecture, Decision support system.

Introduction

With the improvement of living standards and medical quality, people have rising life expectancy. A United Nations population division report shows the changes of the age structure [1]. The global potential support ratio (the number of people age 15-64 per one older person aged 65 or older) has decreased from 12 in 1950 to 9 for today and is estimated to 4 in 2050. The number of persons aged 80 or older is 1.6% of the population worldwide for today and is estimated to be 4.4% in 2050. Every country is facing or will face population ageing and the issues that come along with it. Older people have a significantly greater probability of having multiple chronic diseases than younger people [2]. An estimated 14% of the world's older persons live alone, who might need outside assistance in the case of illness or disability and are at greater risk of social isolation and poverty [3]. Population ageing is an unprecedented challenge for human societies.

With the development of information and communication technology (ICT), pervasive health care, which contributes for the independent life of ageing people, keeping up quality of life and self-sufficiency of ageing people, might be one solution for the ageing society. According to Jakob Bardram, one of the important pervasive health care aspects is home care [4, 5]. Many researchers try to develop home care system for monitoring of vital signs and for improving life quality. Rogers et al have developed a home-based monitoring system for measuring blood pressure [6]. Using of the home monitoring system, detection of essential hypertension has significantly improved. Angius et al have developed a home care system exploiting the DVB-T technology [7]. Using of the set-top box enables untrained or even elderly people can easily use the system. A low-cost base station for the acquisition of 1-lead ECG signal has been connected to the system. Jakkula et al have created a smart home which can perform automated health monitoring and detect anomalies [8]. Based on the context information of interactions with electronic devices, models of resident behavior in the smart home were analyzed.

Decision support system (DSS) is an effective method to improve the price-performance ratio of patient care and reduce medical error [9]. DSS has also been used in home care system for dealing with vital signs and for assisted living. Marschollek et al have developed a home care DSS which can merge smart home and vital signs [10]. Using data from different sauces enables individualized, more personal decision support. Song et al have developed a DSS for home-based rehabilitation of patients affected by chronic obstructive pulmonary disease [11]. This DSS can observe and control physical ergometer training sessions autonomously.

A home care information system contains some key elements: people especially old people, sensor for measuring data, DSS for processing data, and actuator for the implementation of the action. These four elements can form a loop (figure 1), this loop enables people have an assisted living. In order to fully care the elderly, multi sensors, DSSs, and actuators should be used in the home care information system. To efficiently manage the multi sensors, DSSs, and actuators, a high-quality information architecture is very important.

Objective

The aim of our research is to construct a home-centered health information system architecture which can efficiently manage multi sensors, actuators and DSSs.

Methods

Open Services Gateway initiative (OSGI)

OSGI is a service-oriented architecture and has been used in building automation [12]. We use OSGI framework to build up the home-centered health information system architecture. The so-called bundles within the OSGI framework are services. The bundles can be remotely installed, started, stopped, updated and uninstalled during runtime. This means, it is possible to connect or disconnect new services without having to reboot the system. We embedded the sensors, actuators and DSSs in the bundle so that they could work as service and could be controlled individually during run time.

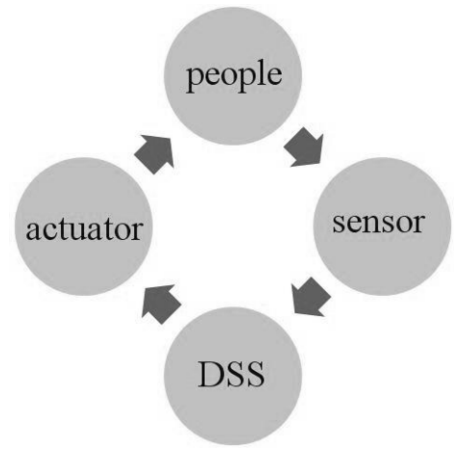

Figure 1- loop in home care information system (decision support system (DSS))

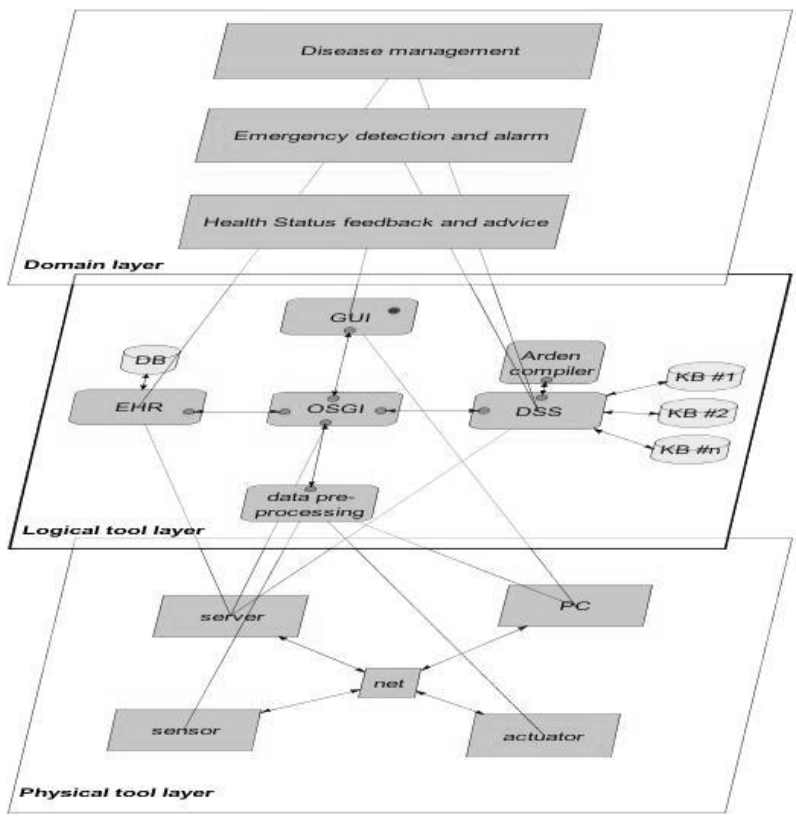

Figure 2- Three-layer Graph-based meta model (3LGM^2) of the proposed home-centered health information system architecture (electronic health record (EHR), graphic user interface (GUI), decision support system (DSS), knowledge base (KB), data base (DB), Open Services Gateway initiative (OSGI), personal computer (PC))

Arden Syntax for medical logical module (MLM)

Health level 7 (HL7) Arden Syntax for MLM is a language to encode medical knowledge for delivering decision support [13]. The medical knowledge is organized into MLM by Arden Syntax. We propose to use Arden Syntax for MLM in the home-centered health information system, because it facilitates knowledge sharing among health care providers. The knowledge base (KB) standardized by Arden Syntax for MLM can provide interoperability with other heath information system (e.g. hospital information system).

We utilized the commercial software "Medexter" [14] to interpret the Arden Syntax. "Medexter" contains an Arden compiler and an interface to connect to other host systems. The Arden compiler supports the Arden Syntax version 2.7.

Results

A service-oriented architecture

We use Three-layer Graph-based meta model ($3LGM^2$) [15] to describe the proposed home-centered health information system architecture (figure2). The three basic tasks of home care: disease management, emergency detection and alarm, as well as health status feedback and advice [16], proposed by Haux et al are shown at the domain layer. In the logical tool layer, OSGI framework is used to construct the service-oriented architecture, electronic health record (EHR), data pre-processing module, DSS and graphic user interface (GUI) are connected as bundles in the framework. The data pre-processing module is connected to sensors (or actuators) and used to provide preliminary data treatment. The meaningful data gathered from sensors are recorded into the EHR. The EHR is connected with DSSs which are used for emergency detection and alarm, disease management, as well as daily assistant. Delivering decision support for people especially old people in home environment contains many aspects, e.g.: fall detection, training controlling, appointment scheduling, etc. Each aspect should have a corresponding DSS. Managing of multi DSSs is a challenge in the architecture; the solution is reported in the next section. The GUI is used for the feedback of the health related information to people who live at home. In the physical tool layer, sensors, actuators and computers are connected by wireless or wired network. Sensors measure people's vital parameters, actuators enable an assisted living.

Managing of multi DSSs

As expressed in the previous section, multi DSSs including KBs should be used in the home-centered health information system. We used Arden Syntax for MLM to standardize the knowledge and packed the Arden compiler into an independent OSGI bundle for sharing of the compiler. This compiler bundle exports all of the packages which are used by other bundles for interpreting MLMs. The MLMs in each KB were connected with the compiler bundle through an interface bundle. MLMs in the same KB can be linked directly according to the logic; MLMs in different KBs are not allowed to fire each other directly. The compiler bundle can be started or stopped. If the compiler bundle is stopped, the MLMs cannot be interpreted. This design is demonstrated in Figure 3.

Case study

We have built a smart home equipped with environment sensors and on body sensors to deploy our home-centered health information system architecture. This smart home is designed for old people who have multiple chronic diseases and live alone. OSGI-framework is used in the smart home to build up the architecture. Some sensors are embedded into OSGI bundles, so they could be controlled during run time. Figure 4 shows most of the sensors in the smart home.

We have constructed two DSSs which were embedded in the OSGI-framework. One DSS is used for rehabilitation training of patients suffering from COPD; the other is used for fall detection. The two DSSs shared one knowledge engine, but the two KBs in the two DSSs were stored and managed separately. MLMs which are stored in the same KB can call each other directly. The knowledge engine can find and fire the MLM through a unique routing.

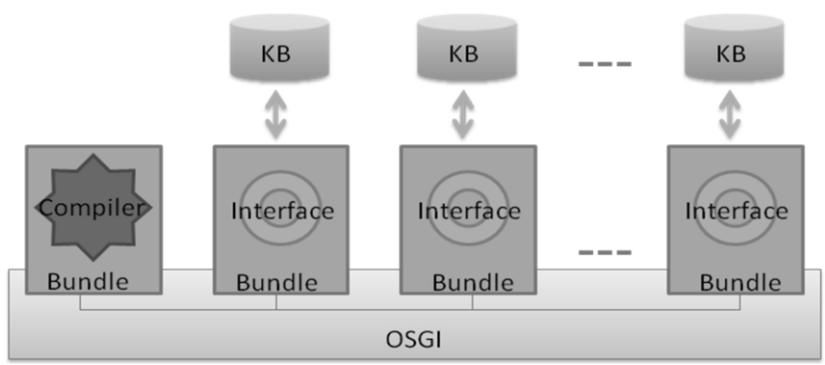

Figure 3- sharing of Arden compiler within Open Services Gateway initiative (OSGI) framework (knowledge base (KB))

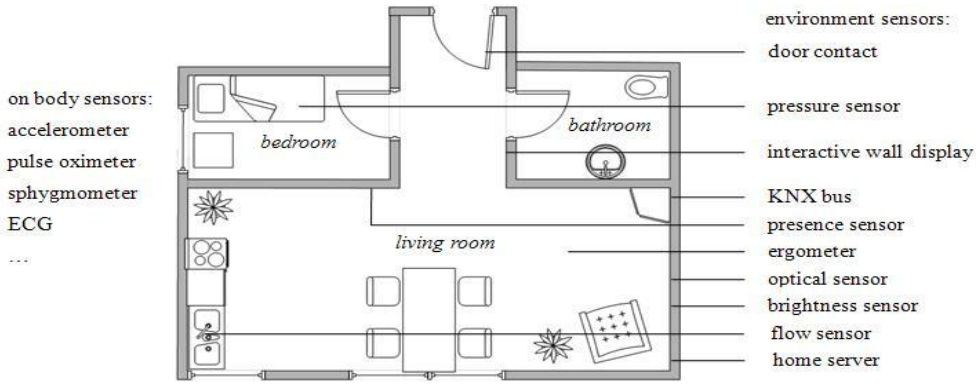

Figure 4- The smart home equipped by environment sensors and on body sensors (Electrocardiography (ECG))

The triaxial accelerometer is one of the on body sensors, it is used for activity detection (e.g.: fall, step, etc) [17]. We take the triaxial accelerometer as an example to follow a work flow of the smart home. An old person takes the triaxial accelerometer and lives in the smart home, once the DSS detects an emergency situation (e.g.: the person fell and cannot stand up alone), the DSS will automatically fire the rules and call for outside assistance. The related information about the fall gathered by the triaxial accelerometer and other sensors will be recorded into the EHR for further treatment and investment.

Discussion

Health-enabling technologies have the potential to significantly improve quality of life and efficiency of health care in aging societies [18, 19]. Sensor-enhanced information system plays an important role in Health-enabling technologies for delivering pervasive health [20]. Haux et al identified four major paradigms of ICT architectures for health-enabling technologies: [16]

- person-centered ICT architectures,
- home-centered ICT architectures,
- telehealth service-centered ICT architectures,
- health care institution-centered ICT architectures.

In this paper, we propose a service-oriented home-centered ICT architecture. This architecture contains sensors, actuators, data pre-processing module, DSSs, EHR, GUI, etc. Our architecture is based on the OSGI framework and can thus change system behavior on the fly. Using health-enabling technologies in home environment for improving life quality of older people has not only technical issues but also social issues. Sensors might not be accepted for various reasons [21], privacy can be a barrier for people's adoption [22]. E.g.: although a camera can detect an unexpected fall, people don't want to install a camera in their own bathroom. The OSGI framework based architecture enables people choice services on demand during run time.

There are also some other related works about using OSGI in home care information system. The SAPHIRE project tries to develop an intelligent healthcare monitoring and DSS on a platform integrating medical sensor data [23]. OSGI was used to build up the multi-services home care platform which communicates between clinic and the patient's home. In addition, this platform manages the execution of the individualized guideline which is modeled by Guideline Interchange Format (GLIF). The Gator Tech Smart House project aims to create assistive home environments that can sense themselves and resident and enables the communication with outside services [24]. To create the Gator Tech Smart House, a generic reference architecture which contains five layers (physical, sensor platform, service, knowledge, context management, and application layers) was built up. In the service layer, OSGI was used to maintain leases of activated services. In the knowledge layer, ontology was connected to the system.

Comparing with architectures in the SAPHIRE project and the Gator Tech Smart House project, our architecture has not only similarity but also difference. The similarity is that all of the three architecture use OSGI framework. The difference is that we use Arden Syntax for MLM to represent the knowledge in the DSSs (SAPHIRE uses GLIF, Gator uses ontology). Knowledge could also be represented in other formats, e.g.: Drools. We use Arden Syntax for MLM because it has been standardized by HL 7 since 1999 and it facilitates knowledge sharing among health care providers. To the authors' knowledge, this is the first integration of Arden Syntax for MLM into OSGI framework.

To deliver decision support for people especially old people in home environment, multi DSSs including multi KBs should be used. Ng et al have developed an architecture for managing multi DSSs [25]. In this architecture, each DSS has its own KB and knowledge inference engine. We think that sharing the knowledge inference engine among the multi KBs could improve its reusability and reduce the system redundancy. The precondition of sharing knowledge inference is that the knowledge in different KBs should have a unified representation form. The KBs which are standardized by Arden Syntax for MLM in our proposed architecture fulfill the precondition. We

packed the knowledge inference engine (Arden compiler) into an independent OSGI bundle. This Arden compiler bundle is responsible for interpreting MLMs in all of the KBs. We evaluated this design with two KBs in a prototype-like laboratory implementation; a formal evaluation with multi DSSs will be done in the further.

Conclusion

In this paper we have introduced a home-centered ICT architecture for delivering pervasive health care. Systems in this OSGI framework based architecture can change their behaviors on the fly. To deliver decision support, HL 7 Arden Syntax for MLM was integrated into the architecture. This architecture could be used in a home environment for improving life quality of people especially old people.

Information Needs in Home Based Healthcare in South Africa

Retha de la Harpe, Jay Barnes, Mikko Korpela

Cape Peninsula University of Technology, South Africa

Abstract

Home based health care (HBHC) is advocated by the WHO "to ensure better accessibility to effective and efficient health care in community and home-settings to improve health and well-being, and contribute to morbidity and mortality reduction". In South Africa the government and many other role players see an increasingly important role for HBHC. Many researchers believe that the evolution of HBHC will follow the socio-technical network evolution. There can be no doubt that the focus is on using information and communication technologies (ICT) to implement HBHC solutions. The objective of this paper is to provide a rich picture of the current situation and needs for improvement in HBHC in South Africa today through descriptive research in one specific case. The longer-term purpose is to identify pain-points that require socio-technical solutions, including but not exclusively ICT-supported solutions.

Keywords:

Home nursing, Home-based healthcare, Socio-technical systems, Landscape modeling.

Introduction

A few decades ago house calls by general practitioners, midwives and certain other medical professionals were far from uncommon. Indeed, in developed countries they were considered the norm. As the burden of illness increased globally, and put increasing pressure on health professionals to speed up their patient throughput, the time (and later expense) of visiting patients at home became prohibitive. For instance Meyer and Gibbons [1] reported that even a decade ago in America house calls were on the decline.

Comprehensive community and home based health care (CCHBHC) is defined by the WHO as "…an integrated system of care designed to meet the health needs of individuals, families and communities in their local settings" [2]. Such care includes physical, psychosocial, palliative and spiritual activities. The goal of HBHC is "…to ensure better accessibility to effective and efficient health care in community and home-settings to improve health and well-being, and contribute to morbidity and mortality reduction" [2].

The report further states that many of the recent efforts to establish home based health care (HBHC) initiatives have been driven by specific emergencies, in particular the HIV/AIDS pandemic [3]. Other major drivers of HBHC are maternal health care and geriatrics, and specific outbreaks of illnesses such as TB and cholera, although poverty driven interventions such as famine and drought relief tend not to fall under the same banner as HBHC. The WHO [2] also report that very often HBHC efforts are not derived from government controlled medical efforts, but rather from various NGOs, religious groups, international donors and even from the communities themselves.

As the burden on health services increases, these services will be pressurized to re-invent themselves [4]. Many researchers (e.g. [4-6] and others) believe that the evolution of HBHC will follow the socio-technical network evolution, as originally outlined by Kling and Lamb [7]. Coiera [4] proposes four "rules" to help guide the design of new socio-technical systems in health services, namely "(1) Technical systems have social consequences; (2) Social systems have technical consequences; (3) We don't design technology, we design socio-technical systems; (4) To design socio-technical systems, we must understand how people and technologies interact". This reinvention is not just limited to under-developed environments. Even such prestigious institutions as the Johns Hopkins Home Care Group (part of the Johns Hopkins University) are having to rethink their approach to this issue [8].

Bentur [9] states that different health care systems have different objectives with respect to the extension of health care service to the home. Amongst these are "providing services to small populations dispersed over large geographical areas, improving access, easing the burden of hospitals and responding to patient preferences." Cost containment without loss of quality of care remains a priority, however.

Although much work has been done in America and Europe on home based health care, it is clear that much benefit will be felt by applying these principles to under-developed countries, where resources of all kinds are stretched the thinnest. Epping-Jordan et al. [10] cite problems identified in the Caribbean, India and South Africa in this respect. Lehoux et al. [6] raise the issue of "information infrastructures" (II), and countries such as South Africa, being on the wrong side of the "digital divide", are particularly susceptible to the issues of scalability.

A number of models for addressing HBHC have already been documented. Ncama [3] cites cases from Malawi, Botswana,

Zimbabwe and South Africa concerning HBHC for families living with HIV/AIDS. She mentions some of the many role players in HBHC, and the confusion amongst them as to what their various roles are, or should be. The Department of Health, NGOs, "concerned citizens", religious bodies, and communities themselves have all, in various places and at various times, started HBHC initiatives.

Technology usage has also come under scrutiny. Although Shaibu [11] documents a non-technology driven HBHC situation in Botswana, there can be no doubt that the focus is on using information and communication technologies (ICT) to implement HBHC solutions. Kling and Lamb [7] describe research into the use and acceptance of medical technology in home care settings. Their findings indicate that, whilst such technology can prove to be useful, it isn't necessarily so, and can have a negative impact of raising false, or at least dubious, hopes amongst the recipients. Lehoux et al.'s issue around scalability is largely reliant on the implementation and availability of ICTs [6].

Access to technology is not the only limiting factor in a South African context. Given that most HBHC will be implemented in the most chronically poor areas, concern will have to be given to the physical security of the technology. Anything requiring the use of a standard PC or mobile phone is likely to suffer from problems of theft. Anything requiring stable power will be subject to the country's continuing national power crisis, and any attempt to overcome this using battery or generator backed equipment will run into the aforementioned security problems.

Research objective of the paper

The objective of this paper is to provide a rich picture of the current situation and needs for improvement in HBHC in South Africa today through one specific case. Within the socio-technological paradigm [4] [7], we must start by developing an in-depth understanding of the social context of HBHC in the case. Thus at this stage the emphasis is on descriptive research. However, the longer-term purpose is to identify pain-points that require socio-technical solutions, including but not exclusively ICT-supported solutions.

Materials and Methods

The Socio-Tech SA project

The study was conducted within the *Socio-Tech SA* project (Made-in-South Africa socio-technical methods and education for local software industry to contribute to socio-economic development) funded by the South Africa – Finland Knowledge Partnership programme (SAFIPA). The purpose of the project is to develop socio-technical information systems development methods for South African software practitioners to contribute to socio-economic and human development in South African communities. Home cased healthcare was selected as the case environment where existing methods will be tried and further developed according to local needs.

The data collection process

Several unstructured interviews were conducted, initially with HBHC coordinators and managers, to obtain an understanding of the HBHC landscape in this specific context. This was followed up with interviewing care givers (providing the home-care service) and nursing sisters (who are assessing and managing the patient's care process). At the same time relevant literature was reviewed to establish what was found in other similar studies. A video recording was made of a care giver visiting patients at their homes to observe the entire care process. This allowed us to observe many other activities that the care giver performs that may not have been mentioned in the interviews. The relevant documentation, such as the care plan and care reports, was also studied.

The emphasis for this study and therefore for the data collection, is on the care service path but from the specific perspective of the care giver, patient and primary supporter. The roles of the professional healthcare professional, facility and authority are all to support the care giver, patient and supporter, i.e., those in the communities.

Results

In this section the results of an initial exploratory HBHC study are given. In order to obtain an understanding of home-based healthcare in South Africa a community in the Western Cape was selected. This community suffers from many negative socio-economic factors that impact the well-being of citizens in such communities. They rely on HBHC to deal with many conditions that are beyond the care service provision of public healthcare. NGOs, NPOs and other interested organisations have taken the responsibility for providing home-care services. These organisations rely on funding organisations or otherwise have to raise their own funds to support an ongoing care service. They report to the Depart of Health, their governing bodies, (in this case the South African Hospice Board) and the respective funding organizations.

The NGO investigated is responsible for the home-based care service to a number of communities around Stellenbosch, a town in the Western Cape province of South Africa. They employ qualified nursing sisters as the healthcare professionals responsible for supervising the care givers; assessing the patients/clients who need home-based care by managing the care plan; and finally taking the responsibility for summarizing the data about the care service for reporting purposes. Healthcare professionals are important stakeholders in these communities serviced by the NGO and are responsible for the care plans of the patients/clients and are familiar with the condition of the community in general. They for example know what are the major problems experienced in the communities and are the first to pick up trends. They rely heavily on information about the care visits and spend too much time processing the data which is still collected from paper patient/client folders, daily and monthly care reports.

The care givers themselves are generally from the respective communities and have only a basic training in home-based healthcare. They are responsible for the ongoing daily care

provision to patients/clients according to a schedule compiled by the responsible sister. Their training is of a very elementary level and they can only provide a basic care service. They often have to provide this service in unfavourable conditions where both their safety and comfort is often compromised. Their commitment and dedication is extraordinary but they feel that the recording of data is taking up too much of their time and that this takes their attention away from their patients.

The actual care service at the home of the patient/client is often attended by many family members and other supporters involved with the patient/client and it is clear that they are actively involved in not only the visit but also taking care of the patient/client on an ongoing basis. The care givers also observe the condition of the home, the availability of food and other supplies, and whether children are looked after. Care givers are well respected and accepted in the communities although in some cases they are refused entry to homes where patients/clients fear that they may be stigmatized, e.g. HIV/AIDS is still a very sensitive issue in many communities where much folklore about this condition still exists. This also applies to some psychiatric conditions. It is therefore clear that the primary care giver, family members, friends and neighbours are important and active participants in a home-based care service. Many of these supporters are ill informed about the condition of the patient and as a result are ill-equipped to care for the patient.

Patients are often referred to as clients since their home care needs may not result from a medical condition, e.g., malnutrition through poverty. In poorer communities their only access to a care service is overcrowded public health facilities which are often at a far distance from their home. The condition of their homes is often inadequate and they do not have the basic necessities and are often not protected from the outside elements. The home-based care service is an absolute necessity for the patients/clients in the poorer communities to provide them with access to a much needed healthcare service. They are often not well informed about their condition and may not be able to assist with administering their own care. Many are illiterate and cannot read the instructions for their medication.

Following from the above findings the landscape model was used as a basis to depict the home-based healthcare service path and the different stakeholders' involvement. The main emphasis of this study is on the needs of the care giver, the patient/client and supporters from the community. Specific research questions were derived from the above to direct further studies to incorporate ICT into an improved home-based healthcare service model to address the information needs. In order to ensure that the different stakeholders' needs are met any design and development of systems with ICT components need to be done with the active collaboration of the stakeholders. The landscape model is an important aid to unpack the complexities around home-based healthcare. It is important to consider the context of home-based healthcare because the different communities are affected by factors that related to their contexts. The context of the HBHC case is depicted in the canvas part of the landscape model illustrated in Figure 1.

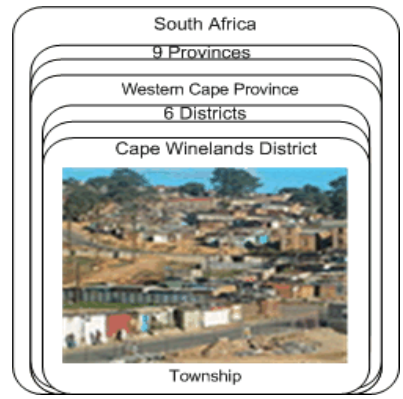

Figure 1 – Context of the Township

In Figure 2 HBHC from the patient's perspective is depicted. Most organizations providing a HBHC service prefer to refer to clients rather than to patients. Although clients sometimes live alone, they live mostly in dwellings with many other relatives or other citizens. In order to address the information needs of the patient the indicated questions need to be answered.

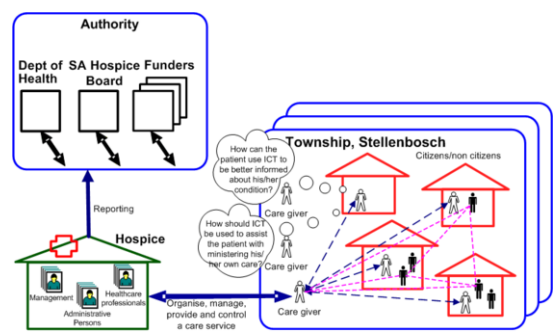

Figure 2 – HBHC from a patient/client perspective

Although the individual members in a community can be referred to as citizens it is also the case that in many communities citizens from other countries also find a home. In some cases the presence of these refugees causes tension in the community where resources are already stretched to a limit. Although there is already a sense of caring for each other present in the community this often is without sufficiently being informed about the condition of the person being cared for and also without knowing who else experience a similar situation. An example is when a person is diagnosed with TB and receives care for it; the supporters of that person may want to know more about TB in order to deal with their perplexities about the condition. Persons fulfilling the role of supporter can gain tremendously from being part of a supporting network where information and experiences can be shared amongst persons dealing with similar situations. In Figure 3, the shaded persons represent the supporters and the dotted

lines indicate how such a network can be formed aligned an interest in a particular condition or issue. The information needs for the primary care giver are to support them when caring for the patient or for interacting with each other and the care giver.

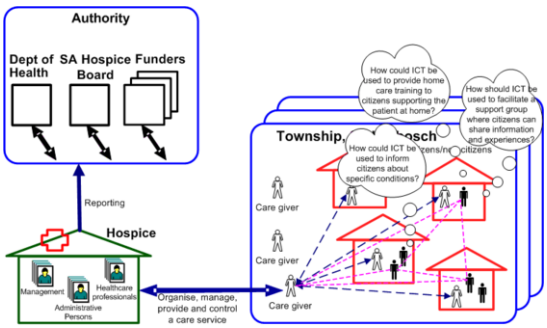

Figure 3 – HBHC from a primary care giver perspective

The care giver's information needs are indicated next as illustrated by Figure 4. They obtain the details for the patient/client's care from the care plan which is kept at the home of the patient. The care plan is compiled by the healthcare professional who does the initial assessment of the patient/client and based on the care needs devise a suitable care plan. They record the details of what they have done to the care plan and write the visit details on the daily care visit report. The patient/client has to sign the report and in the case of illiterate persons to make an "X". The care givers communicate with healthcare professionals to ask for advice when the care plan is not specific enough or the patient has developed another problem. This is not always possible since not all care givers have access to a mobile phone. They meet once a month to give feedback to the NGO and discuss common problems. Care givers not only rely and information to care for the patient but at this stage the manual recording and summarising of data waste much of their time.

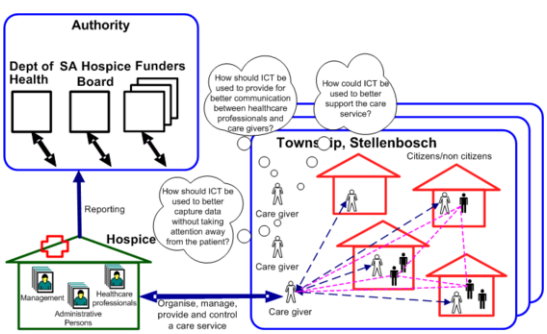

Figure 4 – HBHC from a care giver perspective

Facilities rely on data of good quality in order to manage the home-based care service. They need to know who are the patients and care givers; details about the location of the patients/clients and their care needs as well as availability of care givers are important to assign care givers and to schedule care visits. They need to know how many patients they have in the different areas; what types of care are required; any trends; etc. The paper care plan folders are collected from the homes and brought to the NGO every three months to be updated before being taken back to the homes. A copy is also kept at the facility which means that data is duplicated.

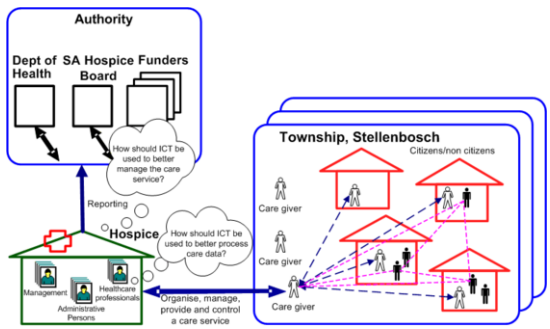

Figure 5 – HBHC from a facility perspective

Not only are organisaions, e.g., NGOs, hospices, etc., responsible for the home-based care service in the communities but are they also accountable to the different authorities. They need data of good quality to report to HBHC situation to the different authorities and each wants it in a different format. Many hours are used to capture, transfer, process, aggregate and summarise data. The primary data is manually collected from the different paper reports and entered into the computer which currently uses spreadsheets to manipulate the data. Little of this manipulation is automatic and the administrator has to still transfer data to the different sheets. Stats are not compiled from the individual source data but instead the aggregated figures are calculated manually and then these are entered in the computer. There is currently no electronic patient record system in use.

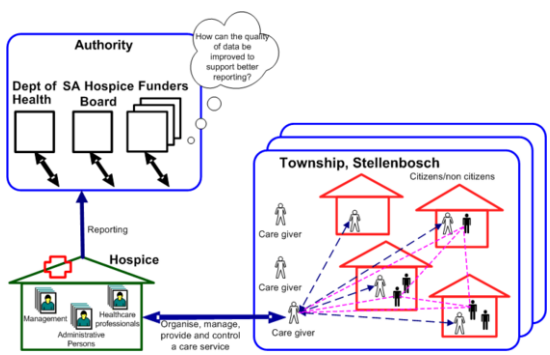

Figure 6 – HBHC from a authority perspective

The current focus of this study is not on the authority's information needs but it already follows from the other perspectives that if their information needs are addressed then ultimately the authorities could also gain. Data of a better quality will improve reporting of home-base care cases, issues, etc. which ultimately enable authorities to better respond to specific community needs. It will also be possible to identify trends in time to cater for a specific condition, e.g., the number of swine flue cases will indicate whether there is an urgent need for inoculation and to put other preventative measures in place.

Discussion

It follows from the above that HBHC is an important and necessary service to citizens in communities that have a need for a healthcare service for citizens not having easy access to public healthcare facilities. It is also clear that often NGOs take the responsibility for delivering such a service. The five landscape models depicting the main perspectives show the care service paths and questions that represent the stakeholders' information needs. The HBHC landscape is even more complex than anticipated and the introduction of technology solutions will add to the complexity. The results confirm that a comprehensive community and home based healthcare (CCHBHC) system is required that will have social and technical components [2]. Any design for such a system will have to follow the four rules [4] for socio-technical design, accepting that social and technical systems have consequences for each and that it is important to understand how people and technology interact. The CCHBHC system should provide for a care service that addresses the needs of the entire care path. In order to obtain a better understanding of how stakeholders interact with technology this interaction where the social and technical worlds overlap need to investigated.

The proposed socio-technical approach provides for close collaboration between the users and developers of a system with both social and technical components. It is also necessary to consider all the other social aspects in addition to where the users interact with technology to cater for an improved care service provision.

Conclusion

The importance of HBHC is not only confirmed but in fact emphasized. In countries where there is severe pressure on an over-burdened healthcare system such a service is crucial and necessary. This may be in contrast with affluent countries where the emphasis is more on comfort for care at home. The stakeholders involved in HBHC are already committed and therefore the only possibility to improve the care service is to consider technology solutions to address their information needs. Further research should be directed to address these needs.

Abstract

Our research work is towards a service that can support senior citizens towards their independent living and active ageing. As it is suggested, physical and cognitive exercise training can contribute to a significant prolongation of personal autonomy and participation in society across prevailing age-related impairments such as cognitive decline. In the current paper, the approach of combination of both physical and cognitive training - adopted by LLM project - is discussed related to other similar projects that have taken place in the area of elderly home care and training. The aim of this work is to describe the technical design details of the integration process of the LLM service, which is based on a Web service architecture and to discuss alternative interface elements to be included in the LLM platform in terms of enabling user accessibility and acceptance.

Keywords:

Cognitive, Training, Elderly, Assisted, Independent, Mild cognitive impairment

Introduction

Substantial advances have been made over recent years in applying technology to meet the needs of older people. In parallel and in accordance with e-Health solutions, the field of Ambient-Assisted Living (AAL) has been developed, aiming on alleviating the difficulties of everyday life for the elderly or people with disabilities in general [1]. Taking into account the increasing number of elderly population in Europe and the identification of its subsequent social and financial consequences, national and European research efforts have focused on such independent living solutions, trying to make an edge on this quickly arising and expanding market [1]. Condition monitoring of the senior and notification in case of an emergency, comprise the most common features of such systems. This offers a sense of safety and reassurance to the elders themselves and their relatives that they will receive the care required in a time of need, without having to be succumbed to intensive care.

On the contrary, the adoption of technology to elderly healthcare systems is doomed to encounter major problems since the vast majority of this population category is unfamiliarized with the available communication and interaction services [2]. Hence, further attention must be paid to the accessibility and understandability of ICT platforms targeted to seniors, which will provide an innovative solution validated and fitted under realistic scenarios [3].

In the last few years several scientific projects have been conducted concerning the amelioration of senior citizens' overall well being. More recently, a number of solutions have been proposed that make use of sensor networks, from audio and movement to micro- and nano- sensors hand, to detect undesirable situations for elderly, like falls. Projects Netcarity [4], INHOME [5], EMERGE [6] and OLDES [7] fall under this category. AttentiaNet [8] and Seniority comprise two already completed projects which aim at improving the quality of assistance and hence quality of life of elder people in Europe by utilizing advanced technologies for telemonitoring and telecommunications. An alternative framework of tele-assistance services which aims to enhance the security of elderly not only in their home as the previous case, is introduced by the MobilAlarm project, where older people are enabled to initiate an alarm call whenever and wherever they need to do so (using GPS; mobile telephony; body-worn alarm devices; service centres; geographic localisation and alerting software). Another, more recently proposed perspective for a solution to the same problem is offered by Confidence [9] and SMILING projects that utilize wearable tags and non-invasive systems to detect mobility patterns and provide a sense of security in the Third Age.

Apart from improving the physical status of senior citizens, several European projects have been focused on the mental health of elderly people attempting to alleviate the difficulties from certain deficits which are common among this population. In accordance with mainstream e-Inclusion targets, this approach's objective is to retain elderly people socially active and more self-reliant for a wider period of time. An example of such projects is the FP7 HERMES [10] project which aims at providing an integrated approach to cognitive care, based on assistive technology that reduces age-related decline of cogni-

tive capabilities. HERMES offers cognitive training through games, while also supporting them in indoor as well as outdoor environments, when necessary. On the other hand, VM (Vital Mind), provides cognitive training by using related psychology, a TV-set and advanced ICT. The reasoning of VM is to enable elders to exercise actively and autonomously in front of the familiar to them television medium. Support for elderly people with cognitive disabilities, and especially mild dementia or Alzheimer's disease, is provided by COGKNOW [11], which aims to develop a cognitive prosthetic device which will help elder "navigate through their day". Functionalities like reminders and support for communication and anomaly detections are planned to deliver this promise. Finally, the Elder-Games project [12] offers the ability to elderly to train themselves through a series of mixed reality games, whose design is specially adapted to their needs, with particular emphasis on the maintenance of their cognitive skills.

Furthermore, several programs have focused on the improvement of elderly people physical condition and especially target to the training of their balance, endurance, flexibility and coordination. Through the use of interactive technology and virtual reality technology, physical interventions have been successfully applied to seniors. An example of this kind of training is a program called TheraWii. It incorporates the use of Wii Balance Board (four accelerometers are embedded at the four corners of the board and record each step (x, y, z coordinates) of the user), a Bluetooth adapter connected to a PC and a game-like interface, with which seniors are interacting. TheraWii offers seniors the chance to combine exercise and entertainment in order to improve their physical health and quality of life.

Though several other categories for applications for the elderly can be identified like mobility aids or medical implants, the aforementioned ones are those more closely related to the Long Lasting Memories (LLM) project [13]. By enforcing the unprecedented approach of simultaneously inducing neural and corporal stimulation in a safe and controlled environment, this platform will deliver an effective countermeasure against age-related cognitive decline, thus significantly reducing chances of mild dementia or Alzheimer's disease appearance. Moreover, the service will utilize a number of remotely operated screens, which will be embedded in the independent living environment and connected to training equipment (like recumbent bikes, ergometers or treadmills). Light exercise will be combined with a targeted set of cognitive exercises, while the environment's sensors will ensure the safe and enduring application of this training, adjusting, intervening or providing motivation according to each person and situation. The aim of this paper is:

i. to describe the technical design details of the integration process of the LLM service
ii. to describe alternative interface design scenarios to be incorporated in the LLM system

Materials and Methods

As already mentioned, the heart of the LLM service is an integrated ICT platform which combines state-of-the-art cognitive exercises against cognitive decline with physical activity in the framework of an advanced ambient assisted living environment.

Thus, the main service is comprised of three independent components:

- CTC, Cognitive Training Component
- PTC, Physical Training Component
- ILC, Independent Living Component

These three independent components will meet the proposed service by means of a server side system, which is comprised of a database and a web service and a decision making system called Central Management System (CMS). The main aim of the LLM system is to offer support not only to elderly people but also to their relatives and families.

Web Service Architecture

The integration aspects of the system are tackled on the basis of a web service and a database. The web service is responsible for providing all methods and functions in order to support the three independent components' and CMS's functions as it is depicted in Figure 1. Moreover, the web service is responsible for the authentication of the system's users according to their role. A database accompanies and supports the web service's procedures. Each of the three components accomplishes a different scope of application and provides heterogeneous data and semantic sources. According to these requirements the proposed architecture must support the integration of the data and the co-ordination of the components' functionalities. One of the major features that the proposed architecture should accomplish is flexibility. The web service's architecture and functionality will be open in order to allow new developments to be integrated and supported by the proposed service in the future developed components (CTC, PTC, ILC). The only prerequisite for the candidate applications to be integrated into the proposed service is to be compatible with the general framework of the service.

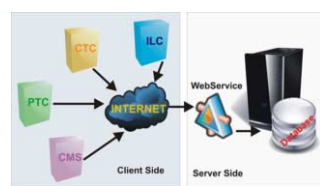

Figure 1- The web service supports the three independent components

The Web Service provides programmatic access to the system's features and services. Developers can build custom applications, tools, and services that correspond to the same services. Typical applications include add/edit and searching for registered seniors, add senior's progress to cognitive or physical training and add information about senior falling or alarms. The Web Service includes the Simple Object Access Protocol (SOAP), Web Services Definition Language (WSDL), and the XML Schema Definition language (XSD). These standards are

supported by a wide range of development tools on a variety of platforms.

The web service provides structures (an example is given in Table 1) as inputs and outputs to all supported methods. All structures and methods are well described by a human readable document which is publicly available. Moreover, each structure is accompanied by an "error" structure in order to facilitate appropriate message exchange with the components.

Table 1 – Structure for senior's demographic data example

```
<s:complexType name="senior">
   <s:sequence>
      <s:element minOccurs="1" maxOccurs="1"
name="senior_id" type="s:int"/>
      <s:element minOccurs="0" maxOc-
curs="1" name="lname" type="s:string"/>
      <s:element minOccurs="1" maxOc-
curs="1" name="birthdate"
type="s:dateTime"/>
……..
   </s:sequence>
</s:complexType>
```

For example, in order to add an activity performed by a senior we use the method shown in Table 2. It behaves as a log file of the senior's progress and activities. The required attributes that must be provided are:

- senior_id: The senior that performs the activity
- ctcactivityid: The CTC Activity that is performed by the Senior
- ctcid: The CTC Component that is used by the senior in order to perform the Activity
- datetimestart: The date and time that the activity started
- datetimeend: The date and time that the activity ended
- score: The score that is achieved by the Senior
- level: The level of difficulty of the performed CTC Activity

Table 2 –C# example using LLM web service method to record user's performance to a certain CTC activity

```
ctcactx = new CTCSeniorActivity();
ctcactx.ID = 0;
ctcactx.senior_id = 16;
ctcactx.ctcactivityid = 1;
ctcactx.ctcid = 1;
ctcactx.datetimestart = new Date-
Time(2009, 6, 21, 10, 00, 00);
ctcactx.score = "16";
ctcactx.level = 8;
ctcsac = AddCTCSeniorActivity(ctcactx,
"username", "password");
if (ctcsac.error.ErrorCode == 0)
ctcactx =
ctcsac.CTCSeniorActivityList[0];
```

A senior has the privilege to use this method only for himself, the Therapist for all of his/her Seniors and the Administrator for all the Seniors. The common scenario is the senior to provide his activities (by LogIn to the LLM system).

Scenarios of Use - Interfaces

Each component, like ILC, CTC and PTC, supports a finite predefined number of activities. These well-described (by the component's providers) activities behave as the elementary entities of the Seniors Interaction. For example, the movement activity in the kitchen may be named "KitchenActivity1", the movement activity in the bedroom may be named "BedroomActivity1". These two activities are different entities. Another example may include the procedure of software that displays 3 screens to the senior (with different multimedia material each time). This may be a CTC Activity. In conclusion, activity is a set of exercises that is treated by LLM system as an Activity. The activity is performed by a Senior and a score for this activity is generated. The proposed system supports a finite number of activities. This number stems from the activities that are supported by the CTC, the ILC and the PTC. These activities are defined by the providers of the components and added to the system once. If a new Activity is available, the administrator is responsible for adding it as a supported activity of the system. Moreover, the term Component is used in order to describe the system that is used by the ILC, CTC and PTC. For example, the Components of the PTC may be a treadmill model1, a treadmill model2, a Wii Balance Board, a Wiimote, etc. Each of the above activities may be available to more than one Component. For example, the "walking" activity may take place at the treadmill model1 or the Wii balance board. If a new Component is available, the administrator is responsible for adding it as a supported Component of the system.

Independent Living Component

The ILC component is based on the eHome system [14], which is comprised of a network of wirelessly distributed operating sensors connected to an embedded system (the e-Home central unit). It includes features such as intelligent learning of normal and exceptional patterns of behavior (dangerous situations or indicators for emerging health or social problems), raising of alarms and controlling of elements which are typical for a smart-home environment. Falls constitute one of the major safety and health risks in older people. For this reason the detection of possible falls plays an essential role in the concept of the sensor technology to be used.

Cognitive Training Component

The CTC is designed to support the cognitive exercising procedure. Any software that is compliant with the web service can be used for this process. Several applications (commercial or not) will participate in the early stages of the service development so as to validate the integration of the system and its usability. The cognitive training procedure contains several kind of exercises that target to specific brain functions, such as memory, attention, etc.

Physical Training Component

The system is completed by the Physical Training Component (PTC) which is comprised by custom training equipment. The only prerequisite for this equipment is to be able to provide exercise performance output. Sub parts of PTC should offer a variety of physical exercising possibilities according to needs and disabilities of each individual. The system will monitor the user's performance progress and will provide feedback using motivation messages and performance indicators. Possible physical training equipment options are: Ergometer Bikes, Treadmills and Wii Balance Board and Wii Remote

Central Management System (CMS)

CMS offers the end user an intuitive, simple to use graphical interface for interaction with the cognitive training system, the physical training system and the independent living component. Besides this, the CMS will be responsible for providing the appropriate feedback to the interacting senior:

- A humanoid avatar, like in Figure 2, will accompany the individual during his/her activity
- Scheduling daily form activities and plan based on previous data (overall performance, physical training, cognitive training)
- Making use of current and previous performance indicators, avatar acts not only as an instructor but also as a supporter, by motivating the individual to achieve expected targets
- Recognizes individual's presence (ILC) and makes a reception call

A television or a touch screen will host the main graphic user interface (GUI) of the system, thus providing elderly a more user-friendly mean of communication with the LLM system. Although touch screens concerned as user friendly input devices, voice recognition and remote controls (wii remote) may be used as the interaction layer between the senior and the system. Apart from providing an abstract schedule for the senior's daily activities, CMS is responsible for displaying the appropriate GUI of the three components, based on the current activity.

Figure 2- Avatar accompanies senior during exercise

User Roles

The system is able to deal with 4 Member Roles. The Role with the most limited access rights is the Relative (User) who is able to get information about his/her relative (senior). More privileges are attached to the Senior (Senior) who has not only the right to see his/hers progress but also to add information about it (through his/her LogIn action to the ILC, CTC and PTC). The Therapist has the authority to add/edit, delete and get results about all seniors that are under his/her supervision (Seniors that are attached to the Therapist). Finally, the administrator has all the available rights [15].

Prototype testing

For the prototype testing a scenario of home installation was selected, as it is shown in Figure 3.The proposed system and especially the web service were tested by contributions of the components' providers. The system testing concerned the efficiency, efficacy, data encryption, data integration and fusion, versatility, code re-usage and cost savings. During evaluation of the web service development, substitute took place in order to provide us with more conclusions concerning the testing. Moreover, some of the methods were redesigned and redeveloped according to the contributors' comments and ideas. As a result, the proposed system is able to support the components; as it was designed for (ILC, CTC and PTC). Although the data semantic information derived from different data source is different from one component to the other, the proposed integration technique seems to be promising for giving a more enhanced meaning to this kind of data fusion providing CMS with information needed for its decision – support system. Last but not least, data encryption techniques provide protection from privacy vioaltion and preserve anonymity of each senior user across the Internet.

Figure 3- Trial site. At Home installation scenario

Furthermore, the combination of the proposed methods and structures may provide a standard on the integration of different components targeting to elderly people ambient assisted living [16].

Discussion

As discussed in the introduction of this paper, an ICT platform which integrates physical, cognitive training and independent living components may be promising for the improvement of elderly people quality of life. Moreover, continuous brain and fitness exercise are considered as one of the most important methods of prevention in elderly dementia and more specific in Mild Cognitive Impairment – MCI (early stages of dementia) [17]. Although seniors with MCI are able to stay at their home, they often visit day care centers. A system as the one proposed to this paper should be able to be applied in both situations. Furthermore, the LLM system due to its open and flexible architecture design, can meet the needs of a wide

range of elderly population, as it is able to integrate any application or device, which complies with the LLM infrastructure. Therefore installation and implementation costs per home can be dramatically reduced and suit to each end user's financial affordability. Future steps include testing of the proposed system not only to senior's homes but also to day care centers. Moreover, trials to different European countries will contribute not only to the further evaluation of the system, but also to the extrapolation of conclusions concerning the benefits of concurrent usage of CTC and PTC by seniors with MCI.

A Configurable Home Care Platform for Monitoring Patients with Reminder Messaging and Compliance Tracking Services

Davide Capozzi, Giordano Lanzola

Dipartimento di Informatica e Sistemistica, Università di Pavia, Italy

Abstract

This paper illustrates a platform based on a general architecture for implementing home care services for chronic patients composed of a Remote Care Unit located at a patient's home and a Health Care Center Unit located at the treating center. The Remote Care Unit may be deployed on multiple platforms including PCs, mobile phones and even embedded devices not equipped with monitor, and may be configured to support many interoperability issues occurring among the parties involved in a health care delivery process. The platform may be tailored to match the specific issues of any chronic disease supporting either data acquisition as well as customized reminders and notifications from the center. Remote Care Unit platforms are also able to exploit multiple channels for acquiring data, including wireless links with medical devices, speech interaction and graphical user interaction. In this paper a couple of applications addressing the needs of diabetic and nephropatic patients developed on top of that platform are also introduced.

Keywords:

Telemedicine, Reminder systems, Outpatient monitoring

Introduction

All the western countries are concerned about the ever increasing trend of their health care budgets. As pointed out in [1] those expenses are now growing much faster than GNP on a world-wide basis, with an expected trend of 5% per year which may render them rapidly unaffordable even on a short term. Most efforts are thus being directed at finding new and effective ways to cope with this problem, and there is a common belief that a generalized adoption of the Information and Communication Technologies (ICT), despite some initial hardships, might help in streamlining the health care delivery process thus saving costs at the organizational context while preserving or even increasing the overall quality and effectiveness of health services [2, 3]. This is also witnessed by the increasing efforts addressing research projects in the telemedicine and e-health related areas aimed at preserving a close contact of patients with health care providers [4] while not at clinical settings. Furthermore, encouraging treatment of patients at their homes besides saving costs may also reduce the stress they suffer during a hospital stay [5]. However special care should be undertaken in developing those applications since a patient is inherently forced into the role of an application user.

This paper introduces our approach to the problem illustrating the telemedicine platform we have developed. The platform is based on a general telemedicine architecture addressing the interoperability issues of chronic outpatients, and makes use of mobile network devices such as cellular phones, palmtops and PDA's in addition to PC's in order to provide an advanced framework for remote clinical monitoring while also facilitating interaction among patients and their families as well as with the health care staff.

Materials and Methods

Addressing communication issues for chronic patients

There is a long-standing debate about the compatibility of ICT solutions with physicians' clinical routines. While at the beginning telemedicine mainly addressed the live transmission of images and biological signals to support *on-line* remote consultations with questionable success, recent achievements in computing, networking and data storage now account for new scenarios modeled on the so called *store-and-forward* paradigm. This approach seems to be more useful in capturing and facilitating data acquisition and interoperability issues for patients who aren't in critical conditions [6]. Networked mobile devices are particularly useful in that case since their inability to guarantee an immediate delivery of data or messages, due to transient coverage, becomes a stronghold in addressing the needs of people on the move.

Such a paradigm turns out to be very useful also for chronic patients who are required to manage a disease by themselves while also being busy with their daily activities [7]. In fact an otherwise normal lifestyle often results in lessening the tie with the clinical settings in charge for the treatments which eventually become unable to promptly notice any situation calling for attention and fail to issue the corrective actions.

The architecture we devised is highly configurable in order to easily adapt to virtually any chronic disease domain. As shown

in Figure 1 it is partitioned into two main interconnected hubs around which several satellite components can be plugged in as spokes. On the left side of the figure the Remote Care Unit (RCU) is located which is centered on the specific monitoring needs of a chronic patient. The RCU exploits mobile devices such as smartphones, PDAs, regular PCs or even plug-computers not equipped with monitors as *gateways* towards the Health Care Center Unit (HCCU) which is shown on the right part of that figure. The information exchanged by the RCU encompasses chunks of the Electronic Health Record (EHR) and log messages about activities to be accomplished on the patient side. The HCCU provides instead reminders about important tasks for a patient concerning his treatment as well as notifications for him about the effectiveness of his/her actions.

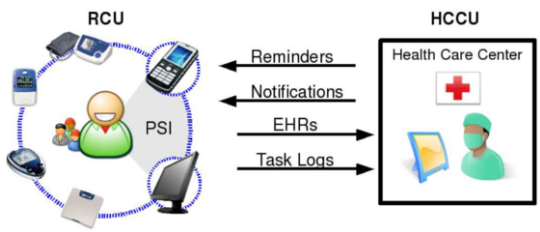

Figure 1 - The functional architecture of the platform.

On the RCU side mobile phones, PDAs and PCs may be interchangeably used as hubs depending on the skills and nomadic habits of a patient. One of their primary purposes is to act as collectors for clinical information required to build up the EHR, which may be acquired through multiple channels in order to guarantee the widest customization possibilities. Among the channels provided by the RCU, the basic one is based on a graphical user interaction. As shown in the figure this requires an explicit interaction of a user with the Personal Service Interfaces (PSI) available on the hub. Since mobile phones, PDAs and PCs greatly differ in terms of the graphical user experience and usability, their selection may be based on the patient profile.

Nevertheless, even though a patient profile may account for successfully adopting PSI for data acquisition, our personal experience has shown that this is definitely prone to errors or cheats especially when young patients are involved. Thus as far as possible we are also supporting automatic data acquisition directly from medical devices towards the RCU gateway exploiting wireless links.

To this aim we use primarily the Bluetooth™ standard which is available on almost every mobile phone and PDAs as well as on a large and ever growing number of medical devices such as scales, blood pressure monitors, heartbeat detectors, pulse oxymeters, glucometers etc. Specific wireless connectivity solutions such as Infrared or ZigBee™ require instead a PC to be used as a gateway.

Finally, we are also supporting data acquisition using the patient's own voice through regular phone calls placed to a dedicated service located at the HCCU. That service is able to model voice dialogues exploiting speech recognition and synthesis capabilities [8]. The possibility of acquiring clinical data with an automated dialogue interview effectively adds voice interaction as a new PSI to the phone gateway and is very important in order to provide a comprehensive PSI suite. This is particularly useful in addressing the needs of those patients whose profiles prevent the use of a graphical interface and no wireless solutions are available as alternatives.

Besides acting as a source of data, the RCU provides reminders and notifications to the patient. Thus a careful tailoring of those functionalities makes it also useful as a monitoring station for a patient's significant person requiring to keep in touch and be always aware of the patient state. Finally the RCU may be endowed with domain specific knowledge for issuing alerts or performing other actions locally without the need to wait for the complete loop involving the HCCU to be accomplished.

The HCCU is responsible for transferring any information acquired into the Hospital Information System, so that it may become available for inspection by the medical personnel. A host of services for monitoring trends in patient data and promptly raising alerts on the physician desktop have already been implemented although they will not be described here since they don't represent the main focus to the paper.

The platform architecture

From an architectural point of view the platform implements a general hardware/software platform which is almost independent from any domain specific data. In that way a particular telemedicine service for monitoring a chronic disease (i.e. diabetes, nephropaties, heart failure, stroke or pulmonary diseases) could be easily implemented on top of our platform exploiting the full power provided by its services with just minor case-by-case customizations required to match domain specific requirements.

The platform is based on the client-server computational paradigm in order to make it available remotely on the territory while at the same time collecting all data at the health care center. The communication between client applications and the server takes place on the internet. In order to enforce the ubiquity of the service, client applications have been mainly developed on mobile platforms with enough computational power and embedding networking capabilities either on a short range (i.e. Bluetooth) as well as on a long range (i.e. GPRS/UMTS and Wifi).

As shown in Figure 2(a) the RCU platform includes a unique pluggable component encapsulating all the Application Logic (AL). This is the only component where domain specific knowledge has been confined, which allows the implementation and configuration of a desired telemedicine service. Any other component shown in the figure and located around AL is totally domain independent. Those additional components constitute the foundation upon which the application relies to exploit local connectivity with personal medical devices (i.e. blood pressure monitors, scales, glucometers, etc.), remote data synchronization with the health care center as well as

scheduling and tracking task execution. The Bluetooth Communication Module (BTC) takes the burden of the connection with personal medical devices thereby allowing us to distribute system intelligence and create clusters of local devices directly managed by the AL running on the mobile [8]. The right protocol for communicating with a specific device is hardcoded into it and automatically selected by the Device Driver Recognizer (DDR) so that AL may be totally agnostic about the syntax and the semantics of communication. A Local Database is set in order to contain a personal copy of the patient Electronic Health Records (EHRs) created with all the measurements collected from local devices and patient task reminders (REM) remotely placed by physicians. Finally, within the RCU a Scheduler Agent (Sched) notifies the AL each time a task is hit during the day, storing back into the Local Database any information about its completion status and outcome.

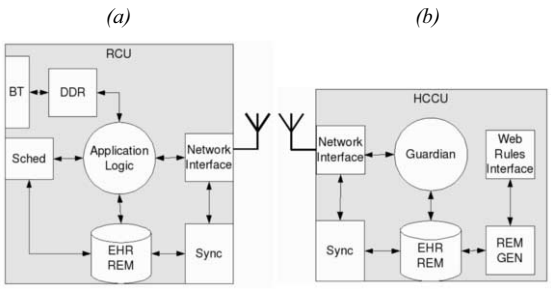

Figure 2 – (a) Remote Care Unit (RCU) architecture. (b) Health Care Center Unit (HCCU) architecture.

A key feature of the architecture allowing RCUs to consistently exchange data with the HCCU is represented by the Synchronizer module (Sync). That module implements a synchronization engine and a protocol based on XML transaction messages for updating, deleting, creating and resolving conflicts within records [9]. Its purpose is to guarantee a regular alignment concerning EHR and REM records stored on the patient side within those available at the treating centre. Finally, a Network Interface module is available for managing communication over the internet. That module, in gateways based on mobile platforms, provides everytime the most convenient channel between GPRS/UMTS or Wifi, while, on gateways based on PCs or plug-computers, it is used to discriminate between ADSL or Wifi connections.

The HCCU architecture is represented in Figure 2(b). Patients' EHRs and REMs are stored on a Local Database which is regularly updated with contributions coming from all remote databases through the Synchronization Agent (Sync) that implements a protocol matching the one available on RCUs. Through the server platform a physician can monitor his patients' health state keeping track of the associated EHRs acquired at their homes according to a personal measurement agenda. The agenda is a task schedule built by the physician through the server Task Definition Interface, a module allowing him to assign the duration and the frequency of a measurement (task) in a human-like way. Once acquired tasks are translated into reminders by a module called Reminder Generator that processes agenda entries and stores the reminders into the database. The server will later exploit this knowledge for monitoring the patients' compliancy to their assigned calendars of tasks through the Guardian. This module analyzes once a day all the EHRs and REMs and rises notifications of value non-compliance or time non-compliance if a patient has taken a measurement whose value falls out of the target range or misses to take the measure altogether. Notifications about non-compliance events are sent to both the physician and the patient through SMS or Email by a Notifier Agent that periodically spools the notifications generated by the Guardian. For those patients being overlooked by a significant other person, notifications may also be sent to that person through an additional RCU acting just as a monitoring station.

The reminder service

Compliance with self-management regimens is often poor, particularly with elderly patients. Nevertheless, since chronic patients play an active role in their treatment, they should carefully take measurements according to the expected time frame mandated by the protocol and avoid missing them altogether [7]. Furthermore chances that patients may forget to take their measurements increases even further for those who are still involved with their daily business.

To overcome the problem a reminder facility has been embedded in our architecture aimed at issuing appropriate warnings to a patient when the due time for a measurement is approaching. The facility is split among RCU and HCCU with different and complementary functionalities. On the HCCU the health care staff responsible for treating a patient may define some rules concerning tasks to be accomplished by the patient. This is based on the rationale that a generic task can be abstracted and applied to any measurement or action to be taken by patients with no concern about which specific chronic disease affects them.

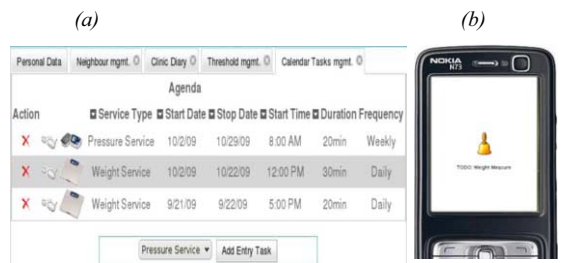

Figure 3 – (a) Task Rule definition interface. (b) A Task Reminder fired up.

As shown in Figure 3 a task rule concerns a specific measurement or action, provides information about its duration (i.e. validity days), its frequency (i.e. daily, weekly, etc..), the time window (i.e. start time and span), and the number of subsequent warnings to be issued within that window if the patient fails to immediately accomplish the tasks. After a rule is ac-

quired, the system starts generating task instances based on it which are then periodically exchanged upon subsequent synchronizations.

The RCU has the burden of tracking tasks by issuing all the expected warnings on approaching due times depending on the platform functionality. Mobile phones and PDAs will do so by emulating an incoming virtual call, while the PC will use loudspeakers and popup alert screens. The RCU monitors if the patient fulfills the request and eventually records the completion status for each task, so that HCCU may be informed about it.

The compliance monitoring service

Monitoring compliance has always been a key issue for chronic diseases, since the better a patient is able to follow a prescribed treatment, the slower the evolution of his disease will be. This becomes an even more important issue in outpatient contexts when patient-staff interactions occur less frequently and the risk of overlooking or missing some important evidence increases. Therefore an explicit service has been embedded within the HCCU with the aim of helping physicians in promptly identifying those patients whose data suggest a critical situation. The information provided by the service may thus be regarded as a fast discriminating mean, so that patients with missing or remarkably abnormal readings can be immediately raised to the physician's attention.

The service is based on warning events which may be triggered by two different information sources. Complying with a given treatment entails first a proper accomplishment by the patient of all the assigned tasks. Since the RCUs inform HCCU about the completion status of each assigned task, rules may be easily provided for generating events concerning missing or missplaced task accomplishments. More warnings may be raised by generic rules checking if any single measurement falls beyond its allowed range or by specialized rules checking some combination of values. The inherent specialization of knowledge required for generating alarms prevented us from building a comprehensive modeling of the whole process for acquiring rules through an easy-to-use graphical interface. Thus while events and their subsequent notifications have been standardized in the system, medical knowledge for raising events must still be represented in terms of small code chunks into the system. This leaves to the interface just the option of enabling/disabling every single rule.

The notification service

After an event has been raised, in order to be effective, it must be notified to the health care staff for proper handling. The first time a physician will connect into the system he will be notified about any pending alarm directly through the graphical interface. Nevertheless requiring physicians to connect it's not an option since even before the availability of a home care system they were accustomed to schedule regular visits for chronic patients just every one or two months with no other contact in between. Thus in order for the system to be really effective we realized that it should proactively send notifications about significant events rather than wait for connections to occur. In order to generalize the solution, the capability of sending notifications has been factored out and encapsulated into a separate module which is dynamically fed up with events raised by the compliance monitor. The physician configures the module by indicating how and when (i.e. preferred time) to be notified about those event. The module collects any notification occurring since the last submission, and forwards them to the physician using the preferred mean (i.e. SMS, E-Mail, etc.) If requested, the same notifications could also be sent to the patient by forwarding them to the RCU.

Results

The platform developed has been used to implement two separate prototypes, one supporting young patients affected by Type 1 Diabetes Mellitus (IDDM) and the other one addressing uremic patients undergoing Peritoneal Dialysis (PD). In the first case young patients are required to measure their glycemia levels several times a day, usually before meals or snacks, in order to adjust the insulin therapy which is administered either through a pump (continuous infusion) or injections (boluses). In this case we have been unable to acquire readings automatically since glucometers are classified as medical devices and to date there is no approval by the Health Ministry for wireless ones. Measurements are thus inserted into the RCU by the patient using the GUI which also offers the opportunity to annotate data with additional information concerning meals and personal notes. Periodical synchronization with HCCU ensures that physicians may have those data promptly available for inspection.

Figure 4 – The Remote Care Unit for the peritoneal dialysis application.

Patients undergoing PD instead of being treated with external hemodialysis at a hospital setting, fill their abdominal cavity regularly at home with a suitable solution cleaning their blood by osmosis. For them it is mandatory to keep pressure and weight under strict control since that information acts as a clue for potential cardiac failure and helps in controlling daily urine volume preventing overhydration. The RCU in that case has been configured for automatic data acquisition since both a scale and a blood pressure monitor equipped with Bluetooth

were found on the market, as shown in Figure 4. Given that the dynamics of body hydration is very rapid, according to the protocol it is mandatory to take frequent measurements always at the same time. Thus reminders were used to alert patients when time for the next schedule approaches. This application is currently undergoing an evaluation phase at a major hospital located in northern Italy. Four patients previously accustomed to write down blood pressure and weight measurements regularly were enrolled into the trial. The physician summoned all of them in a single day at the beginning of which he held a short preliminary statement illustrating the benefits of the trial. A short demonstration session was held and at the end each patient has been provided with a personal package including a complete RCU and an operating instruction booklet. Separate session training were then held in order to make sure that at the end of the day each patient was fully convinced to take part in the trial and be able to successfully operate the RCU. The trial is expected to last for at least 6 months with the aim of comparing the decrease in the physician workloads ensuing the reduction of face-to-face encounters with the quality of service delivered to patients.

Discussion

The scientific literature illustrates several implementations of telecare applications addressing the needs of chronic patients. Nevertheless each one of them seems to target a specific problem instance which restricts its applicability to the very same domain for which it was designed despite the potential demand for similar applications. Our efforts have been directed exactly in the opposite direction since they try to address the problem at a higher level by providing a sound architecture and an implementation platform which may be easily configured for building applications in different domains, each one with its own distinguishing features.

In addressing IDDM we configured the patient RCU with a GUI for acquiring data, notifications were adopted just for text messages issued by physicians and no reminders at all were used. Nevertheless, since the application is meant for young patients it has been almost mandatory that parents stay informed about the state of their kids. Within our platform the problem has been solved quite easily introducing additional RCUs for the parents configured with notifications as their only service. In that case notifications include either messages issued by physicians as well as readings so that parents can be informed about their kids even when they are away from home (e.g. at school).

In designing the uremic patient application the wireless module has been exploited for acquiring data on the RCU given the availability of suitable devices. This greatly simplifies data acquisition for elderly patients who are not proficient with the use of PCs or mobiles. Furthermore, since it is important to take measures at fixed times and the application is meant for elderly patients, the reminder service has been extensively used. Finally in both applications, once data become available to the HCCU, additional services have been implemented to help physicians in promptly identifying critical situations.

Conclusions

This paper illustrates a configurable platform for delivering home care services to chronic patients. The platform represents a solid foundation providing several common facilities which may be exploited out-of-the box in order to rapidly assemble and configure specific applications in different medical domains. The platform is composed of several Remote Care Unit stations located at the patients' homes and a Health Care Center Station located at the treating center. Both have been designed in a highly modular fashion in order to keep any issue concerning the representation of medical knowledge and its related processes separate from technological and networking issues. Configuring the platform we were able to implement two prototypes addressing separate medical domains and exploiting different input capabilities. In both cases we were able to provide patients and their family caregivers with proper advice concerning the therapies by embedding separate chunks of medical knowledge on remote stations and at the health care center.

Daily activities and fall risk – A follow-up study to identify relevant activities for sensor-based fall risk assessment

Peter L. Reichertz Institute for Medical Informatics, University of Braunschweig – Institute of Technology and Hannover Medical School, Germany

Abstract

The demographic change will lead to an increase in the incidence of falls in the elderly. Technological progress allows for unobtrusive physical activity measurement with miniature sensors, e.g. accelerometers. Yet it is unclear which activities or activity patterns are associated with an increased fall risk. The aim of the research for this paper is to identify daily physical activities associated with a high fall risk. A one-year follow-up study was conducted with n=50 geriatric patients who took part in a telephone interview to assess fall events, their consequences and a set of daily physical activities. Descriptive analysis of the data shows that there are marked differences between fallers (n=21) and non-fallers (n=29) in the overall activity level, the amount of shopping activity and associated locomotion, and in the intensity of light household work. The results confirm that there are differences in typical daily activities between fallers and non-fallers that may be used as parameters to enhance fall prediction models.

Keywords:

Accidental falls, Motor activity, Assisted living facilities, Sensors

Introduction

It is a well-known fact that the future demographic development will lead to an increase in the elderly population, both in absolute and relative numbers [1]. This change in population composition will lead to a rise in the prevalence of chronic diseases and in multi-morbidity. Physical activity is an important and independent factor in the etiology of many chronic diseases, including diabetes mellitus, cardiovascular diseases, musculoskeletal diseases, certain types of carcinomas and even affective diseases (e.g. [2, 3]). Along with the recent development of wellness and exercise support systems, this has led to a rush in sensor-based activity recognition/analysis projects in the last decade, because automated assessment even during long-term periods in daily life has become feasible due to the rapid development in sensor technology and mobile computing power.

With regards to the demographics, however, falls are a predominant problem. It is estimated that the annual cost of falls and their consequences amounts to $20 billion in the U.S. [4]. Furthermore, falls are associated with a high risk to retain functional limitations as well as the so-called 'post-fall syndrome' that comes along with an increased fear of falling, leading to a vicious circle of ever-decreasing activity leading to a loss of muscle mass (sarcopenia) and so on [5]. Individual fall risk is associated with gait parameters that can be measured with miniature accelerometers [6-8]. There is also evidence showing that persons with a high risk of fall-related fractures risk tend to be less active in their daily lives than those with a low risk [9].

One of the most relevant applications of activity measurement could be to identify persons with a high fall risk by identifying gradual changes in daily activity patterns. Thus, persons with an increasing risk may be prompted to get timely intervention to reduce individual fall risk [10]. It remains unclear, however, what types of activities and activity patterns are correlated with a high fall risk.

Therefore the aim of our research for this paper was to identify those daily physical activities which are the most relevant for identifying persons with a high fall risk.

Materials and Methods

Study population

The basic population for this study are all elderly persons, the selection population were all patients that received in-patient treatment at the Department for Geriatric Medicine of the Braunschweig Medical Center, Germany, between April 24th and October 18th, 2007. These patients were enrolled in a previous study that investigated the use of sensor-based gait parameters to identify persons with a high fall risk [11]. Altogether n=119 subjects with a mean age of 80 years participated.

For the study at hand these 119 persons were contacted by mail and asked to participate in a one-year follow-up study to assess their fall history and their daily activity profile. 50

subjects agreed to participate in our study and gave written consent.

Telephone interviews

In order to identify an adequate telephone assessment tool to record daily activities, the first author conducted a search for suitable questionnaires on the Internet and in corresponding scientific journals. To the authors' knowledge, the only activity questionnaire that has been designed and validated for elderly people is the questionnaire presented by Voorips et al. [12], containing ten questions concerning the amount of light and heavy household work, the number of persons, rooms and floors taken care of in the household, meal preparation, number of stairs walked daily, shopping, and mode of transportation when moving in one's hometown and for shopping. Each answer is scored on a scale from 0 (low activity) to 4 points (high activity).

Within the interviews, fall history was assessed following the criteria proposed in the *Prevention of Falls Network Europe* consensus [13]. A 'faller' was defined as a person having sustained at least one "unexpected event in which the participants come to rest on the ground, floor, or lower level" ([13], p.1619).

The interviews were conducted by co-author AR, a registered nurse and diploma student at the Peter L. Reichertz Institute for Medical Informatics.

Data analysis

We chose two different approaches for data analysis. The first method was a descriptive analysis of the point values for all ten questions. As the answers are scored on an ordinal scale, we chose to calculate rank sums for each score and to present the results in a bar diagram (Figure 1).

The second approach was an exploratory analysis of the relevance of each activity score. We chose to calculate the *information gain* and to rank the parameters accordingly. In information theory, the information gain is defined as the amount by which a parameter is able to decrease total entropy. It is measured in *bits* and used by several pattern classification algorithms to choose a parameter to split a dataset, e.g. by the C4.5 algorithm [14].

Results

Descriptive analysis of rank sums

Figure 1 shows a bar diagram with the rank sums for each activity sub-score and the sum of all scores. While differences between the two groups of fallers (n=21) and non-fallers (n=29) can be seen in the rank sums of all activity parameters, the largest differences can be observed for the mode of locomotion when shopping, the overall amount of shopping activity, engagement in light household activities such as washing the dishes or dusting. The smallest rank sum differences are found for the number of stairs walked daily and – correspondingly – the number of floors in a person's living surroundings. Finally, the overall activity sum score also shows an obvious difference between fallers and non-fallers.

Information gain analysis

The calculation of the parameters' information gain yielded only three activity sub-scores with a positive gain value. These are shown in Table 1. All other sub-scores were not applicable to split the given dataset into fallers and non-fallers.

Table 1 – Information gain value ranking of activity sub-scores

activity parameter	information gain [bits]
shopping – mode of locomotion	0.155
amount of shopping activity	0.127
amount of light household work	0.119

Discussion

First of all, it can be observed that – despite the limited sample size – there is marked difference in overall activity between the two groups, indicating that persons with a high fall risk have a low activity intensity. This can be observed in the activity sum score, but also in all sub-scores. This confirms results of Stevens et al. who report a higher activity in patients who do not sustain a fall-related fracture, provided that they do not suffer from any limitations in terms of an ADL-score ≥ 0 [9]. For patients with such limitations, the odds ratio is reported as 3.2 to sustain a fall-related fracture.

Among the different daily activities that have been measured by our questionnaire, the largest differences between the two groups can be observed in the intensity of shopping activity on the one hand and in the mode of transportation or locomotion when going shopping on the other hand (Figure 1). This result is confirmed by the highest ranks of these two items in the information gain calculation (Table 1). It may be concluded that persons who have a high fall risk either do not or less often go shopping on their own or – if they do so – rather use a means of transportation (car, public transportation) that does not require advanced motor skills such as bicycling or walking – possibly with shopping bags. The reasons for this may be manifold. Firstly, as fall risk is related to functional limitations in performing demanding motor activities such as repeated sit-to-stand transitions or alternate steps [15], shopping may be regarded as a demanding task requiring multiple physical skills, and – as such – changes in this activity might be regarded as an early indicator for the onset of motor functional limitations. Secondly, falls often lead to the 'post-fall syndrome' [5], leading to a vicious circle of increasing fear of falling, subsequent limitation of personal and social activities, leading to a further increase of fall risk, and so on. In our sample, 61.9% (13 out of 21) of the persons who fell within the study year had at least one fall event before. The post-fall syndrome therefore might be one of the reasons for shopping

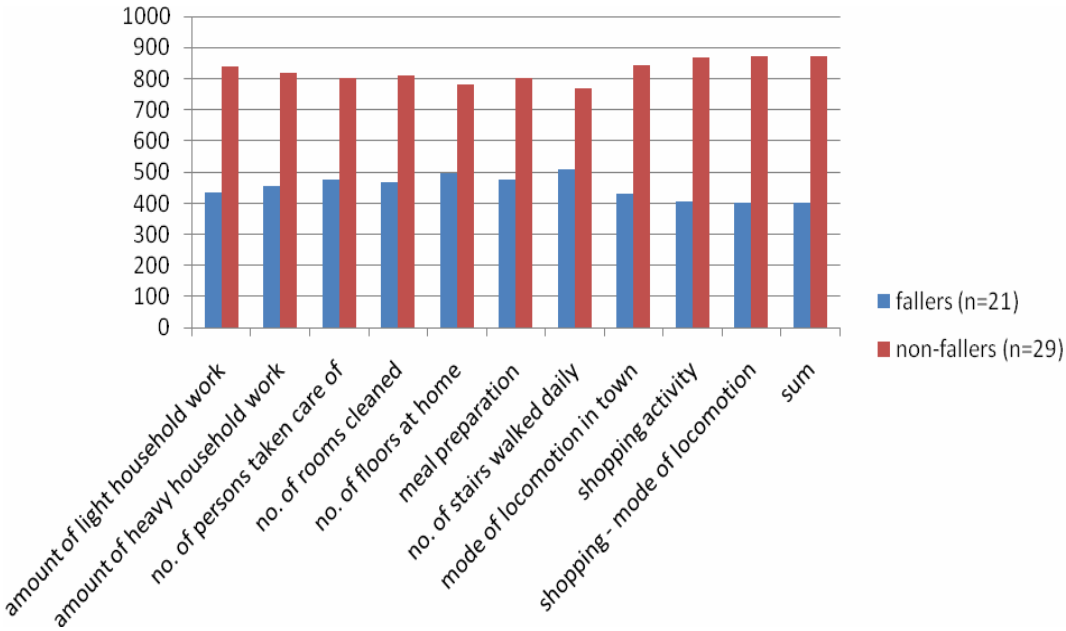

Figure 1- Rank sums for ten different daily activities and the sum score for fallers (n=21, blue) and non-fallers (n=29, red) in the one-year follow-up study

activity differences. It might be noted that shopping is regarded as one important social activity for elderly persons, so that these limitations may have severe consequences for social participation and integration.

From a technical perspective, the sensor-based assessment of shopping activity is possible if a mobile sensor system is used. In a previous study with five elderly persons wearing a multi-sensor system, the authors were able to identify shopping activity with an accuracy of 79.9% [16]. In another study it has been shown that activities such as driving a car (90.4%), riding a train (86.4%) and riding in a car (64.0%) can also be identified with a moderate to good correctness, if a classification is trained on individual sensor-based movement data [17]. Thus, it can be concluded that the two most important daily activities that were identified by our study setup can be assessed automatically and therefore can be used to enhance fall prediction models.

Apart from shopping activity, group differences have also been shown for the amount of light household work. This indicates that these activities. however 'light' they are, tend to be more difficult for persons with a high fall risk. This, again, may be interpreted as a consequence of the progressive loss of functional motor ability on the one hand [18], and of the post-fall syndrome on the other hand [5]. The activities explicitly mentioned in the validated questionnaire are washing the dishes, sewing and dusting. It might be argued that these require heterogeneous motor and cognitive skills that cannot be distinguished by just one question. Nevertheless, this item seems to be a further indicator for an increased individual fall risk.

It may be argued why the authors have not chosen to use established scores such as the *Katz Index of Independence in Activities of Daily Living* (ADL) [19], the *Barthel Index* [20] or the *Instrumental Activities of Daily Living* (iADL) [21]. These are clinical scores that help to assess functional limitations, and they are scored by external reviewers. The crucial factor, however, is that they do not allow to quantify physical activity and therefore were deemed inappropriate for our purpose.

Limitations

First of all, the sample is not very large (n=50). Only 42% of the persons contacted agreed to participate in our follow-up study. Apart from declining due to personal reasons that were not specified any further, several persons had moved to unknown locations and quite a few had died already. This sample therefore should not be regarded as being representative.

Secondly, the authors have chosen a descriptive analysis instead of a confirmatory analysis of the data in order to avoid the problem of multiple testing. The authors believe that this

kind of analysis using the rank sums is rather appropriate for the task at hand.

Finally, it may be argued that the set of activities that is assessed by the questionnaire only provides a rough approximation of daily activities, and that it lacks the granularity necessary for an all-encompassing activity assessment. The authors agree with that, but – as stated above – are not aware of another, more detailed questionnaire that has been validated for use with elderly people.

Conclusion

This is the first study that has assessed the relationship between the amount of different daily activities of elderly people in their home environment and their fall risk with regard to the potential of sensor-based activity measurement. A low amount of or no shopping activity, a passive way of individual locomotion when going shopping and the inability to perform even light housework could be identified as indicators of a high fall risk in our follow-up study. Our future work will be directed towards the sensor-based, long-term assessment of these activities to provide a further, valid source of information to be integrated in automated fall prediction models.

Acknowledgments

We thank our clinical partners of the Department for Geriatric Medicine at the Braunschweig Medical Center for their invaluable support, especially Dr. Hubertus Meyer zu Schwabedissen, Dr. Gerhard Nemitz and Cornelia Kühling.

Abstract

With the development of electronic personal health records, more patients are gaining access to their own medical records. However, comprehension of medical record content remains difficult for many patients. Because each record is unique, it is also prohibitively costly to employ human translators to solve this problem. In this study, we investigated whether multilingual machine translation could help make medical record content more comprehensible to patients who lack proficiency in the language of the records. We used a popular general-purpose machine translation tool called Babel Fish to translate 213 medical record sentences from English into Spanish, Chinese, Russian and Korean. We evaluated the comprehensibility and accuracy of the translation. The text characteristics of the incorrectly translated sentences were also analyzed. In each language, the majority of the translations were incomprehensible (76% to 92%) and/or incorrect (77% to 89%). The main causes of the translation are vocabulary difficulty and syntactical complexity. A general-purpose machine translation tool like the Babel Fish is not adequate for the translation of medical records; however, a machine translation tool can potentially be improved significantly, if it is trained to target certain narrow domains in medicine.

Comprehension, Translating, Consumer health information, Medical records.

Introduction

Providing patients access to their own health records is key to the new patient-centric health care paradigm, in which patients take charge of their own health by becoming active participants in their health care decisions [1]. In line with this new paradigm, in many countries, including the US, patients have the legal rights to access their own medical records. The recent development of electronic personal health record (PHR) systems holds the promise to significantly improve patients' access to their own records.

While PHR is helping more patients gain access to their records, comprehension remains an obstacle if PHR is to fulfill its full potential to motivate and empower patients to better their health [2]. Medical records typically contain complex information intended for healthcare professionals, not consumers. The challenge posed by the comprehension of health-related material is even greater for patients who are not fluent in the language in which the records are written. According to a 2004 US Census Bureau report, there are 33.5 million foreign-born residents in the US, representing 11.7% of the total population. Undoubtedly, while many foreign-born residents may well be fluent in English, many others cannot speak, read or write in English, or may never reach an acceptable level of proficiency in that language.

With respect to PHR applications in the US, foreign-born patients' lack of English proficiency may well place them in the "hard-to-reach" category, similar to low-literacy English-speaking patients. It has been argued that we particularly need to reach out to such patient population, since low literacy has been associated with poor self-care and poor health outcomes, including increased mortality and hospitalization [3, 4] and, ultimately, increased social and health-care costs. If consumer applications such as PHR do not address the needs of the "hard-to-reach" populations, we run the risk of widening the existing health disparity gap.

One way to minimize this gap for the non-English-speaking segment and to allow them to benefit from the PHR availability is by providing translations into the patients' native languages. Many US hospitals provide on-site translation services for patients (timely point-of-care services). Further, an increasing amount of patient education materials are available in languages such as Spanish. A number of studies have been conducted on the needs, methods, barriers, and benefits to providing human multilingual translation services [5, 6]. However, within the context of medical records, resorting to human translators is not feasible, since each record is unique. Thus, anticipating the need for record-specific, accurate translations, machine translation emerges as the next best option. We believe machine translation is worth exploring in this context. The goal of this pilot study was to test the efficacy of a popular general-purpose freely-available machine translation tools on patient medical records. English was the source language and the target languages were Spanish, Russian, Korean, and Chinese. Even though this study was meant as a proof-of-concept endeavor, our general goal is the development of machine translation tools

specifically devised to render accurate and understandable medical record information.

Background

Machine Translation can be defined as an automated system that takes a given text as input (source language) and produces as output the translation of that text into a target language. The translation process as such is performed using special computational programs, dictionaries, vocabularies, glossaries, and different sets of linguistic rules [7].

Although the concept of machine translation (MT) has been around since the 30's and 40's, it gained popularity only in the 60's and 70's, when it was touted as the perfect solution for text translation, capable of rendering translated text of human translation quality [8]. However, MT lost much of its appeal when it became evident that those were unrealistic expectations. With the expansion and application of natural language processing (NLP) techniques and stochastic methods to MT in the mid to late 80's, there was a renewed interest given that these techniques produced superior results. Further, despite its potential for numerous errors and disjointed narrative, people became aware that raw, unedited MT output could be used to obtain the gist of a document. More recently, the widespread use of MT in the Internet opened the door to other novel uses and applications, such as cross-language information retrieval [9] and multilingual communication [10].

While it is still true that post-editing is unavoidable for first-rate translation quality, the use of controlled language and vocabularies can go a long way towards reducing the need for intense revisions, especially when restricted to specific domains or to particular types of documents, as in the case of meteorological reports. This is also the setting for electronic health records: they are contextually restricted to the medical field and the narrative can be quite formulaic. An MT system specifically tailored to medical texts could potentially be used on English electronic health records to make them understandable to speakers of other languages.

One such system, engineered by the Pan American Health Organization [11], has several micro-glossaries with domain-specific vocabularies, two of which are geared to the medical field: *Super Medical* and *Patient Information*, with consumer health vocabulary. The fact that the Pan American Health Organization Machine Translation System (PAHOMTS®) is limited to three languages (English/Spanish/Portuguese), however, made it unsuitable for our project, as we were also evaluating the application of MT to other languages not included in this system, namely, Russian, Chinese, and Korean.

Another system, the open source medical speech translation system (MedSLT), has been described in the literature. The prototype of MedSLT translates spoken questions from English into French, Japanese and Finnish in three medical subdomains (headache, chest pain and abdominal pain) using a vocabulary of about 250-400 words per sub-domain [12]. Since the goal of this project was not to evaluate how well or how appropriately different MT systems perform, but rather, whether the use of unedited MT output represents a viable option for translating electronic health records, it was important that the same software be used for all languages involved. This consideration, along with the wide availability offered by the Internet translation tools, pointed to Altavista for this experiment.

Methods

Materials and Reviewers

We retrieved 11 publicly available sample medical records from two websites as testing materials:

- MedLEE demo site (http://zellig.cpmc.columbia.edu/medlee/demo/)
- MT (Medical Transcript) resources (http://www.mt-resources.com/index.html)

They include discharge summaries, surgical notes, admission notes, and radiology reports. For a translation tool, we selected the freely available Babel Fish by AltaVista (http://babelfish.altavista.com/), as it is one of the most easily accessible and widely known online translating tools.

A total of five reviewers participated in the study. All reviewers were proficient in English and a native speaker of either Chinese, Korean, Spanish, or Russian. All were medical informatics researchers with graduate school level of education or higher.

Procedure

Identifying the testing variables

In order to identify operational variables that measure the quality of the translation, we first translated one record using Babel Fish from English into each of the four different languages mentioned in the introduction. In order to review the quality of the translated text, we used two testing variables which had also been identified as important evaluation criteria for MT by other studies [13, 14]: understandability and correctness of the translated sentence. Regardless of the language in which they are written, medical records are difficult to understand because they are fairly technical documents that require a certain level of expertise to understand. Moreover, they often contain abbreviations and grammatically incorrect phrases and expressions. In order to control for such intrinsic confounding factors we added a third variable: understandability of the original sentence.

Establishing the evaluation rules

We divided each text into its component sentences, to assess the translation quality of each sentence via a 3-point Likert scales. We considered each sentence to be a self-contained chunk of information. In order to promote consistency in using the scale and set uniform parameters, an initial detailed instruction sheet with examples were developed and distributed to the reviewers. First, four reviewers coded 39 sentences collected from 2 records. The coding results were shared and discussed in a group meeting, and the rules and instructions were further refined. For example, when the translator failed to translate certain terms the reviewers were instructed to replace the untranslated terms with blank spaces

and determine the understandability and correctness as if the untranslated terms were missing.

Coding the translation

The specific coding steps were similar to those described in (13). They were as follows:

1) Rate the understandability of the translated sentence first without seeing the original sentence in the source language (English) and without consulting any dictionary.
2) Rate the understandability of the original sentence in English without consulting any dictionary.
3) Rate the correctness of the translated sentence in terms of accuracy, by comparing the translated sentence to the original sentence. Dictionaries may be consulted in this step.

Reviewers then rated 213 sentences collected from 8 records, following the finalized evaluation rules and instructions.

Reliability of the translation evaluation

In order to test the reliability of the human evaluation results, we trained a second native Spanish speaker (the fifth reviewer) in the use of the same evaluation rules just described, and then assessed the level of agreement between the two reviewers. After practicing with the evaluation rules on 15 sentences, the second Spanish reviewer independently rated the quality of the Spanish translation of 65 sentences which were randomly selected from the 213 sentences. We observed the percentage of agreement in each variable. In addition, the level of agreement in each variable was tested with a McNemar test. In the McNemar test, the categories of "partial" and "no" were merged as one.

Analysis of the sentence characteristics

In order to identify factors that affect the accuracy and comprehensibility of the translation, we investigated the characteristics of the original sentences. We extracted three kinds of text features using an in-house built Natural Language Processing (NLP) tool: HITEx (Health Information Text Extraction) [15]. We also measured the overall readability of each sentence using the readability analysis tool called HIReA (Health Information Readability Analyzer) which assesses the text readability based on three types of text characteristics [16].

Results

Translation quality

Reviewers found the translation to be understandable only between 11.27% and 31.46% of the time (Table 1). In other words, for each language tested, reviewers found that the vast majority of translations were either incomprehensible or partially comprehensible. In contrast, the majority (65.73% to 85.73%) of the original English sentences were deemed comprehensible by all reviewers.

When examining the correctness of the translations, we found that only a small percentage (7.98% to 11.74%) of the Chinese, Russian, and Korean translations were deemed correct by the coders. Spanish translations did comparatively better, with 33.80% deemed correct. Nevertheless, for all languages involved, the majority of the translations we not totally correct. Due to the nature of medical records, which contain critical information, the lack of accuracy in translations is very problematic.

Table 1 - Understandability of the original and translated sentences and correctness of the translated sentences

		Spanish	Chinese	Russian	Korean
Translation understand-able?	Yes	31.46%	11.27%	14.55%	19.25%
	Part.	43.19%	26.29%	20.19%	28.64%
	No	25.35%	62.44%	65.26%	52.11%
Original Sent. Understand-able?	Yes	88.73%	66.67%	80.28%	65.73%
	Part.	10.33%	25.35%	13.62%	26.76%
	No	0.94%	7.98%	6.10%	7.51%
Translation Correct?	Yes	33.80%	7.98%	11.74%	9.39%
	Part.	44.60%	7.51%	10.33%	24.88%
	No	21.60%	84.51%	77.93%	65.73%

Reliability of the translation evaluation

When comparing the results of the two Spanish coders on the 65 test sentences, we found that they agreed with each other 71.31% to 80.00% of the time on the three parameters. This agreement rate is acceptable considering that the two reviewers spoke somewhat different Spanish dialects, as they came from two different Spanish-speaking countries. When applying the McNemar's test, statistically significant differences ($p<=0.01$) were found in their judgment of comprehensibility and correctness of each sentence, but not in the comprehensibility of the original sentences.

Analysis of the sentence characteristics

The correlation analysis (Table 2) shows that the sentence length is a significant feature that negatively affects the understandability of the original sentence and the translation quality. In other words, longer sentences were less likely to be understood or yield a correct translation. Both vocabulary features (vocabulary familiarity score and out of dictionary word ratio) were significantly correlated with the understandability and correctness variables. The use of familiar terms showed positive correlations whereas the use of out-of dictionary terms showed negative correlations. No part-of-speech categories consistently and significantly correlated with understandability and correctness. The readability score (how difficult a sentence is) was positively correlated with understandability and correctness.

Table 2 – Correlation analysis: sentence characteristics and translation quality

	Sentence length	Vocab. familiarity score	Out of dictionary word ratio	Readability score
Understand-ability of original sentence	-0.2722*	0.2949*	-0.4267*	0.3554*
Correctness of translation	-0.4393*	0.1201†	-0.2502*	0.2664*
Understand-ability of translated sentence	-0.3625*	0.1996*	-0.2702*	0.2588*

* *correlation coefficients are significant at 95% significance level,*

† *correlation coefficient is significant at 90% significance level.*

The mean values of text features that showed significant correlations with translation quality and the understandability of the original sentences are presented in Table 3. "Yes" answers received a weight of 2, "no" answers a weight of 0, and "partial" a weight of 1. The average original and translation understandability and translation correctness were categorized into two groups: incomprehensible or incorrect (=<1) and comprehensible or correct (>1).

Table 3 - Mean values of text features that had significant correlations with translation quality and vocabulary familiarity score

		Number of words per sentence	Vocabulary familiarity score	Out of dictionary word ratio	Readability score
Original	Incompr.	17.6920	0.6784	0.2427	-0.6450
	Compreh.	12.9700	0.6737	0.0904	-0.4740
Transl.	Incorrect	14.4670	0.6774	0.1024	-0.5010
	Correct	8.6136	0.6612	0.0894	-0.4180
Transl.	Incompr.	15.2540	0.6684	0.1087	-0.5260
	Compreh.	9.2670	0.6854	0.0817	-0.4010

As suggested by the text feature analysis, the main cause of incomprehensible and incorrect translations appears to be the technical domain-related medical vocabulary on one hand, and irregular or complex syntax used by the original English sentences on the other. Longer sentences tend to have more complex syntax and a higher chance of containing difficult words. To a lesser extent, the vocabulary and syntax also made the original English sentences fully incomprehensible or partially comprehensible at times.

Upon closer examination, ambiguous and out-of-dictionary terms are the two main vocabulary problems for MT. Take the example of the sentence "Patient has had small to moderate amounts of serous drainage at site". The word "moderate" has several dictionary definitions and different parts of speech. In the original sentence, it is used as an adjective with the meaning "of medium or average quantity or extent." However, it could also be used as a verb to mean "to lessen the violence, severity, or extremeness of," which apparently was how the word was wrongly interpreted by the MT system when converting the sentence to Chinese, Korean, and Spanish. The system that we used is a general purpose, general-vocabulary application. Thus, some medical terms were missing from the system's dictionary and were not translated. This rendered some sentences not understandable. We rated all incomprehensible translations as incorrect.

Discussion

Although there is an increasing need for automated translation of medical content, especially in the context of personal health record applications, there has been no reported study on the efficacy of applying existing MT technologies to patient medical records. Our pilot study evaluated the quality of a popular general purpose translator by applying it to a novel use, that is, to the translation of 213 sentences from patient medical reports, from English into four different languages.

This study found that the translation results are quite frequently incomprehensible and inaccurate, for all four languages tested. While the original English sentences were not easy to read, the majority of them were deemed totally comprehensible by each of the coders. However, the reverse was true for the comprehensibility of the translations. In addition, in terms of accuracy well below 50% of the translations were deemed (totally) correct in each language. The results are not equivalent or uniform in the languages tested. The machine translation system performed noticeably better in the English to Spanish direction than in other language translations. One possible explanation for this may well lie in the fact that English and Spanish are much more similar (word order, inflections, etc.) than English and Chinese, Korean or Russian.

Our findings suggest that off-the-shelf and general purpose machine translation systems in their present state are unlikely to be of real help to non-English speaking-patients in understanding their medical records. First and foremost, the incorrect translations could seriously misinform patients and lead to more serious safety problem. Because of liability issues, it is hard to imagine any PHR application would incorporate such a tool unless the accuracy of the translation improves dramatically. The comprehensibility of the translated sentences is also too low for practical use.

We do believe, however, that machine translation could be dramatically improved to the point in which it could be useful and helpful for the task at hand, starting with the possibility of including medical vocabularies or glossaries if one so desired. It should be pointed out that by our observation the majority of the incorrect translations appear to be associated with medical terminology. However, the irregular or complex

grammar structure of medical reports is also a source of errors. Machine translation is a type of natural language processing application and with regards to medicine and medical texts, it has been more successful when applied to more narrowly defined domains (e.g. radiology). If a machine translator is trained for a very narrow domain in medicine (e.g. medication instruction), and is equipped with a comprehensive medical vocabulary, it would become much more reliable, as the vocabulary would be more controlled, and so will the grammar. When dealing with a specific and relatively small domain, the syntactical variance that needs to be addressed is reduced and can be more easily tackled.

One of the limitations of this pilot study is the relatively small sample size and number of coders. The coders of this study are bilingual, have an educational level and exposure to medical terminology well above those of the average US population, and presumably higher than those of the average non-English speaking population in the US. It is to be expected that an average non-English speaking patient would find even fewer of the translated sentences understandable. Another limitation is that the Babel Fish translator we used may not be the best machine translator. As mentioned in the background section, the PAHOMTS system would most likely produce higher quality translations and improve the results for Spanish, but it could only be used for much fewer language options. Nevertheless, based on our experience with the PAHOMTS and other machine translation tools, comprehension and accuracy are commons issues for all machine tools.

In order not to leave one of the most in-need populations – the people with limited or no English proficiency behind – in the development of personal health records, we intend to further explore the use of MT technology. As a start, we would focus on one or two narrow and relatively simple domain areas and employ strategies (e.g. translate the translation back to the original language) for quality assurance purposes.

Measurement of the Utilization of an Installed Electronic Health Record

Prashila Dullabh, Adil Moiduddin, Elizabeth Babalola

Department of Health Care Research, NORC at the University of Chicago, USA

Abstract:

For the past decade, adoption of electronic health records (EHRs) has been proposed as one of the most viable approaches to improving the United States health care system [1]. *Although there is evidence that EHR adoption is slowly progressing, current methods of assessing adoption have yielded significant variance in estimates of EHR utilization. We conducted an environmental scan consisting of a review of the literature as well as a series of discussions with health center and health center network representatives and experts in the field to understand the current state of EHR adoption and use in the United States and assess the feasibility of developing a systematic approach to tracking EHR usage.*

Computerized medical records systems, Utilization, Policy making, Automated reporting, United States health care reform

Introduction

In the face of rising costs and concerns about quality in the United States health care sector, an emphasis has been placed on the critical role that health information technology (IT) will play. Electronic Health Records (EHRs) have great potential to improve patient outcomes, increase patient safety, and bring about overall improvements in the quality of care delivered. EHRs also have the potential to be a critical enabler of a high-performing healthcare system having demonstrated improvements in the quality, increased adherence to guideline-based care, enhanced surveillance and monitoring and decreased medication errors [2]. As a result, the President, Congress and others have placed a great deal of attention on promoting widespread adoption of EHR technology. The 2009 American Recovery and Reinvestment Act (ARRA) authorized approximately $36 billion towards health IT, with a significant amount to promote the '*meaningful use' and adoption of certified EHRs* [3].

Despite the profusion of initiatives aimed towards accelerating the adoption of EHRs and the rising impetus for practices to adopt EHR systems, the health care sector is far behind other industries with respect to IT adoption [4]. At the same time, EHR adoption in the United States lags significantly behind that of many other Western countries [5]. Estimates of ambulatory EHR use in Austria, Belgium and Australia are 75%, 78% and 79-90% respectively while Denmark, England, Finland, the Netherlands and New Zealand have reported rates above 90% [5]. A report released by Harris Interactive showed that the United States was far behind all but a few European countries in terms of EHR adoption [6].

A great deal is also unknown about the use of specific features of EHRs in the United States, and there is no standard set of methods that reproducibly measures their utilization. Issues that contribute to making the question of quantifying adoption challenging include the lack of a clear definition of an EHR, a lack of standards to measure usage and inconsistencies in how EHR functions are described across the myriad of vendor products that are available today.

This study addressed the following questions:

- What are the major methods that have been used to assess EHR adoption and utilization?
- What are the core functions of EHRs?
- What is the nature of EHR use in ambulatory care settings? Which functions are most commonly utilized?
- What are the challenges and barriers associated with adopting and using EHRs?

Methods

Key research activities involved a literature review, review of EHR surveys and a series of key informant discussions. The initial literature review was used to identify EHR surveys and a framework for categorizing EHR functions. To contextualize what we learned from the literature review on EHR adoption and use we conducted a series of discussions with informants in the field.

We conducted a review of published and unpublished literature to identify previous studies of EHR adoption. We systematically searched electronic databases including PubMed, Academic Search Premier, MedLine and CINAHL and conducted targeted Internet searches using the Google and Google Scholar search engines in order to identify government reports, unpublished articles and other relevant resources.

Results of the literature review were also used to identify surveys for analysis of survey instruments. In identifying which surveys to include in our analysis, we used several criteria. First, we focused our search on surveys of ambulatory settings published within the last six years. Second, we sought to identify surveys utilizing nationally representative samples. Finally, surveys of EHR use in health centers were specifically included. To the extent that any additional surveys were deemed to be of use in our study, we also included them in our analysis. We conducted an examination of the common EHR features examined in the surveys to inform development of a comprehensive list of key clinical and administrative features within an EHR system within an EHR system. In developing this list, we also reviewed the initial Institute of Medicine (IOM) core functionalities of an EHR system [7] and expanded on this by examining the HL7 functional model and the Certification Commission for Health Information Technology (CCHIT) criteria for ambulatory EHRs.

To further inform the study, we conducted a series of discussions with three major ambulatory EHR vendors, two key informants that have expertise in the area of health IT adoption in ambulatory care, and five health centers representing a small subsample of early EHR adopters and their protégés. In engaging with discussants, we sought to identify the common features and functions available in the EHR system, assess use of specific system functions, and EHR capabilities for capturing usage data. In addition, we also made an effort to understand vendors' technical architecture and capacity for reporting on system utilization and quality measures.

Results

Published estimates of EHR adoption are of varying quality. In a report comparing existing surveys assessing EHR adoption up till the year 2008, it was found that very few were adequate to accurately capture the state of EHR use in the United States [7]. In addition, while there are many studies which measure the rate of adoption of EHRs, there is significantly less information to be found regarding actual physician use of EHR features. The Robert Wood Johnson Foundation report titled *Health IT in the United States: The Information Base for Progress* defined adoption as "a process that, for measurement purposes, captures the acquisition, installation and use of EHRs" [8]. It was recommended that, in order to achieve accurate results, EHR adoption surveys should assess these three domains. However, many surveys of EHR adoption merely assess system availability (acquisition and installation) rather than the degree of system utilization (use).

Surveys Selected for Review

Our literature search identified three recurring national representative surveys that assessed EHR adoption. The National Ambulatory Medical Care Survey (NAMCS) and the National Hospital Ambulatory Medical Care Survey (NHAMCS) both included the same sections measuring EHR use in practices. The Center for Studying Health System Change Community Tracking Study Physician Survey included a section assessing the use of IT in physician practices.

Four other key national studies emerged. The National Survey of EHR Adoption was developed by the DesRoches et al. study team and represents one of the most comprehensive studies on EHR adoption to date. Also included was the Commonwealth Fund National Survey of Physicians and Quality of Care, a 2003 survey which explored physicians' use of IT tools. The Medical Group Management Association (MGMA) conducted a 2005 survey to assess the adoption of health IT in their medical practices.The2007 Office Systems Survey which was administered by the Centers for Medicare & Medicaid Services (CMS) as part of their Doctors Office Quality Information Technology (DOQ-IT) initiative was also included in our analysis.

Two surveys of health center adoption of health IT emerged. A 2005 survey administered by the Community Clinics Initiative to assess information management in health centers was identified. Finally, the 2006 National Association of Community Health Centers (NACHC) survey of Health Center Use of Electronic Health Information was the first national measure developed to specifically access health center adoption of health IT.

A total of nine surveys were included in our final analysis. Six of these studies were large-scale national studies that measured EHR adoption, two were surveys developed to assess health IT use in health centers, and one was a statewide survey assessing EHR functionality and the level of physician use of the specific functions.

Categorization of EHR Functions.

Based on information gathered from review of the IOM core functionalities, the HL7 EHR functional model and the CCHIT criteria for ambulatory EHRs forty EHR features were identified and organized into the following eight function-based categories: "Organize Patient Data", "Compile Lists", "Receive and Display Information", "Order Entry (CPOE)", "Decision Support", "Communication and Connectivity", "Administrative and Billing Support" and "Other".

EHR Use

Health center network representatives and ambulatory care practices reported that in general the more basic, or first tier, EHR features such as those of patient demographics, recording patient vitals, documentation of notes, entering medication and allergy information, problem lists, referrals, billing (particularly in smaller practices), medical summary and entering insurance information features were the most frequently used. These were common functionalities that were cited as having been implemented in almost all practices.

Meanwhile, features such as drug formularies and eligibility checking received lower levels of use or were not used at all. In the case of drug formularies, some practices reported that it was difficult to have a comprehensive formulary as all insurance plans may not have chosen to participate. Health plans also tended to change their formularies and formularies in the EHR may not necessarily have been updated in a timely way. This resulted in providers not being very keen to use the drug formulary function. Eligibility checking functions were report-

edly very hard to integrate into the EHR. Instead, practices sometimes chose to make use of the eligibility checking through their existing practice management systems.

Additional second-tier functions included clinical decision support such as smart forms, alerts and reminders, drug interaction checking and clinical guidelines. Second tier functions were often not implemented when the systems were first installed and there also appeared to be variability in terms of the size of the practice; larger practices seemed to be more equipped to implement more advanced clinical decisions support features compared to smaller practices.

Electronic Exchange of Laboratory Information

The electronic exchange of lab results was one of the features of the EHR system that was most commonly used. In most instances, EHRs had established unidirectional interfaces with national labs or local labs and sites were receiving results electronically. Many sites reported that establishing interfaces with hospital labs was more difficult and oftentimes there was reluctance on the part of the hospital to establish a results interface with ambulatory care providers and health centers. In cases where results interfaces were established, providers routinely used the EHR to order labs that resulted in printed lab requisitions. A few sites reported supporting bi-directional lab interfaces, but this was not common. However, sites reported a growing trend to support bidirectional interfaces with labs and discussions with vendors also indicate that they are encouraging bidirectional lab interfaces at initial installation.

There was also a growing trend to use point of care (POC) devices in providers' offices for a variety of lab tests including HbA1c, simple blood chemistries, pregnancy tests, HIV testing and cholesterol testing. In cases where POC devices were being used, the extent to which they were integrated with the EHR varied. This resulted in health centers and practices supporting a variety of different workflows.

E-Prescribing

The practices reported that a majority of the e-Prescribing (eRx) done was only partly electronic. In cases where e-Prescribing was being used, the provider entered the prescription into the EHR using the eRx software. However, three different approaches were being employed to route the prescription to the pharmacy:

- *Fully electronic* – Prescriptions are sent electronically to pharmacies in a paperless process, through the SureScripts-RxHub network. In this case, the prescription is electronically routed to the pharmacy information system.
- *eFaxing* – Prescription information is electronically faxed to pharmacies. Using this process, a fax normally prints at the pharmacy and the pharmacist manually keys in the prescription into the pharmacy information system.
- *Prescription printing* – A hard copy script is printed and handed to the patient who fills the prescription at a pharmacy of choice. Among those practices capable of e-Prescribing, this approach is generally used only in instances where patients are not able to indicate which pharmacy they will print the script at or if the pharmacy does not support e-Prescribing.

In general, sites tended to use the eFaxing approach. Reasons cited for this included that, at the time of initial implementation, there were many barriers related to e-Prescribing and that there did not appear to be any financial benefits of the technology. Furthermore, while larger pharmacy chains are generally capable of receiving prescriptions electronically, many smaller pharmacies are not capable of this due to the high cost of implementation on the pharmacy end. A final barrier cited was the inability to use eRx for controlled substances due to current Drug Enforcement Agency (DEA) rules for eRx [9].

Clinical Decision Support

Practices and health center networks reported having EHR systems with Clinical Decision Support (CDS) modules. These modules were capable of numerous functions including providing drug interaction alerts, clinical practice guidelines for particular chronic diseases, and prompts and reminders for health maintenance. Sites also reported that EHR vendors are increasingly making available knowledge resources that allow for context sensitive help from within the patient record. While the availability of this function was not commonly reported, a few sites had implemented it and regarded it as a very useful tool for providers.

Many CDS functions were in the second-tier, i.e. most likely implemented only once the EHR system had been in use for a while. Providers also tended to use those functions only as it was relevant to their practice and specialty.

Several informants also reported that their health centers and ambulatory practices had implemented alerts and reminders in their EHR system in order to support preventive services and e-Prescribing. Although this feature has great potential to be an extremely valuable EHR tool for increasing patient safety, informants indicated that many physicians experienced problems using the drug interaction alerts component of the CDS. Some perceived these alerts to be intrusive or annoying. Others felt the information offered by the alerts was redundant and unhelpful. In both cases, the alerts often acted to interrupt and slow down physicians' workflow. As a result, some practices allowed physicians the flexibility of selectively turning off or adjust the threshold for these warnings. Sites reported that it appeared clinicians significantly took advantage of this option.

Use of Other EHR Functions

In terms of more advanced EHR functions, several discussants reported that they were beginning to use their EHR for referrals and for specialty reports such as radiology reports. Generally, mid and large sized practices were more likely to be expanding current EHR use in this direction. Very few health centers and ambulatory care practices reported being able to receive radiology images. In cases where this was supported, the EHR generally received a link to the image which was hosted by an external Picture Archiving and Communication (PACS) system. This was the preferred method as radiology images can be fairly significant in size and many small and mid-sized provider offices did not have sufficient bandwidth to

support the transport and storage of large radiologic images. In general, practices reported that receiving the radiology report was far more important to them than receiving the images. In cases where practices were not able to receive radiology or other reports electronically, most had at the very least implemented scanning technology that enabled them to scan the paper reports into the electronic health record.

Interoperability and Standards Support

The Health Level 7 (HL7) messaging standard is being used widely to support electronic exchange of information between provider practices and hospital, national and local labs. However, while most sites report using HL7 for messaging, many of them are yet to implement HL7 V2.51. Many of the health center networks that we spoke to used either commercially available or homegrown interface engines and reported that they spent significant amounts of time establishing interfaces with different labs and providers due to the significant variability in the implementation of the HL7 messaging standard.

With respect to data content standards, the National Council for Prescription Drug Programs (NCPPDP) Script is being used for eRx. Most practices also reported the use of the SureScripts-RxHub network to connect to retail pharmacies. Sites included in this study generally supported use of the Continuity of Care Document (CCD) while there were a few sites that indicated that they supported the Continuity of Care Record (CCR) for patient summary data. Although sites reported having the capability to exchange the CCD, they had limited experience in actually exchanging patient summaries as they reported that many sites that they routinely interact with were not able to receive the CCD.

For sites that supported electronic exchange of lab information, there was virtually no active use of the Logical Observation Identifiers Names and Codes (LOINC) for lab results. Sites reported that lab results from national, hospital or local labs were not LOINC encoded even though the EHRs are able to receive LOINC codes. Similarly, there appeared to be no use of SNOMED-CT.

Reporting on Quality Metrics

Unlike monitoring of usage, most of the sites we conducted discussions with were using EHRs to assist in reporting on different quality metrics. Many of the health center networks were reporting on the HRSA quality indicators [10], which include blood pressure control in hypertension, HbA1c in diabetics, pap smears and mammography for women, immunization for children less than 2 years, depressions screening and colorectal cancer screening. Sites did not directly use their EHR for quality reporting, but instead populated a registry or a vendor supplied reporting database with the subset of information that was needed for quality reporting. This approach was preferred over running reports against the EHR production database due to concerns of system speed and response times. Sites also reported that many EHR systems lacked out-of-the box reporting capability for quality metrics and they opted to use more sophisticated tools in the form of registries or custom databases with enhanced reporting tools.

Assessing EHR Usage

Efforts to monitor EHR use varied tremendously from site to site, dependent in part on the availability of IT resources, size of the organization, availability of canned reports within the EHR system and size of practice. In very few cases had sites implemented any robust capability to assess utilization of EHR functions. In general, smaller sites, or sites that relied largely on their vendor for IT support reported that they were not routinely collecting or reviewing usage data. In most cases, the vendor audit logs were a source of information to assess which providers had accessed different aspects of the EHR. This was largely done in the context of ensuring the security and privacy of patient records. Where sites were monitoring system usage at a granular level, they were either working with the vendor IT team to create the report or had independently undertaken the task of building customized reports (this was mostly done by networks). In almost all cases, significant customization was required in order to extract the kind of information sites were interested in from the EHR.

For practices that were currently measuring EHR usage, there was a significant variability in the granularity of data collected. All sites were able to track usage both at the practice and at the physician level and assess the use of specific functions. Usage data was easier to access around basic features such as the use of templates, completing insurance information, signing of forms and keeping track of the functions within the EHR system which had been disabled. However, monitoring clinician use of more advanced features such as CDS was particularly challenging.

Discussion

This study provided valuable information regarding the nature of EHR use and implementation in health centers and practices. There existed variability in the EHR functions that are used based on practice size, practice specialty and length of time for which the EHR has been implemented.

Commonly used EHR functions. Review of current EHR use in ambulatory care settings suggests that in all practices (small, mid and large) there are certain basic clinical and administrative functions that are commonly used. The clinical functions used include encounter notes, medication lists, allergy lists, problems lists, and order entry functions focused around lab order entry and results delivery. The use of eRX appears to be increasing dramatically but current use is still limited.

Current use of Standards. Despite the availability of industry accepted standards and CCHIT requirements that certified EHRs support certain standards, current use in ambulatory care settings appears to be limited. While most sites report using HL7 for messaging many of them are not yet on HL7 V2.51. With respect to data content standards, NCPDP Script is being used for eRx. Some sites report that they generate a CCR or a CCD but have had limited experience in its use as organizations that they interact with often are not able to accept summary documents in this format. There is virtually no active use of LOINC for lab results even though lab results are one of the most commonly used functions within the EHR.

Use of EHRs for Quality Improvement. Practices of all sizes also report that they support clinical decision support functions related to eRx largely in the form of drug interaction and drug-allergy checking. More comprehensive clinical decision support functions tend to be more common in larger practices and may include the use of smart forms, preventive care reminders, clinical guidelines and knowledge resources. While sites report using EHR data for quality reporting, in most cases a third party registry product or alternate database is used to generate these reports. Ambulatory EHRs have limited out-of-the box capability for quality reporting and oftentimes, due to concerns regarding system speed and response times, quality reporting is not done off the production database.

Sites using clinical decision support for eRx report that this has improved medication management and compliance with formulary. Additionally large practices that utilize smart forms and other forms of decision support report higher compliance with evidence-based practices and improved outcomes. An objective assessment of impact of EHR use on quality improvement cannot be made given the rudimentary nature of how EHR utilization is being tracked. Additionally while sites are reporting on quality outcomes the lack of standardization of measures and how these should be collected and reported also presents a challenge

Challenges and Barriers in utilization of EHRs. Our findings suggest that barriers to EHR use are multi-factorial. In many cases cultural resistance of providers and other clinical staff result in limited use of available functionality. In other cases the implementation of new systems have not accounted for good integration with clinical workflows and consequently providers use workarounds or may stop using certain functions entirely. Particularly in the context of CDS sites reported numerous challenges to ongoing use of this feature. In some cases the immaturity of the vendor product and usability issues were cited as reasons for non-use. In some cases regulatory challenges presented a burden for example, sites reported that due to DEA rules they were not permitted the use of eRx for controlled substances. Many of our informants reported that they encountered numerous challenges in exchanging information electronically with labs or other provider sites. Limited interoperability resulted both from lack of use of standards and tremendous variability in how certain standards were being implemented.

Conclusions

Understanding EHR utilization and ongoing challenges and barriers to use will have important implications across the medical and health IT industries. Study findings indicate that there is a common set of EHR functions that all practices are likely to have purchased and that sites would be capable of implementing. Most EHR vendors have capability to track usage of these common functions even though they may not all support the same robust reporting capabilities. By providing tools to health centers and networks to monitor EHR utilization these organizations would be better equipped to promote meaningful use and adoption proactively.

Acknowledgments

This study was funded by the Assistant Secretary for Planning and Evaluation (ASPE) at the U.S. Department of Health and Human Services (HHS).

Measuring Use of Electronic Health Record Functionality Using System Audit Information

Watson A. Bowes, III

Department of Medical Informatics, Intermountain Healthcare and University of Utah Department of Biomedical Informatics, Salt Lake City, UT

Abstract

Meaningful and efficient methods for measuring Electronic Health Record (EHR) adoption and functional usage patterns have recently become important for hospitals, clinics, and health care networks in the United State due to recent government initiatives to increase EHR use. To date, surveys have been the method of choice to measure EHR adoption. This paper describes another method for measuring EHR adoption which capitalizes on audit logs, which are often common components of modern EHRs. An Audit Data Mart is described which identified EHR functionality within 836 Departments, within 22 Hospitals and 170 clinics at Intermountain Healthcare, a large integrated delivery system. The Audit Data Mart successfully identified important and differing EHR functional usage patterns. These patterns were useful in strategic planning, tracking EHR implementations, and will likely be utilized to assist in documentation of "Meaningful Use" of EHR functionality.

Keywords:

Medical Records Systems, Computerized/utilization

Introduction

Early in this decade, adoption of Electronic Health Records (EHRs) was identified as an important factor in improving healthcare in the United States [1]. In spite of this recommendation, recent EHR adoption rates in the United States are low, with only 4% of ambulatory physicians using a 'fully functional' electronic record system in 2008 [2]. With the passage of the American Recovery and Reinvestment Act (ARRA) of 2009, over 19 Billion dollars was targeted for healthcare information technology (HIT) projects to accelerate the adoption of EHRs and other technology. Much of this money will be used for incentives for ambulatory physicians and hospitals that demonstrate "meaningful use" of HIT [3].

At this time, demonstration of "meaningful use" of HIT is still being defined by committees that report to the secretary of Health and Human Services. Early indications are that " meaningful use" will be measured by determining use of certain core functions found within most EHRs. Core functions were identified by the Institute of Medicine and categorized into eight groups including Health Information and Data, Order Entry Management, Results Management, Clinical Decision Support, Population Management, Patient Support, and Administrative Processes [4]. These categories of core functions were used successfully in a recent nation-wide evaluation of EHR adoption [2].

We expect that the adoption rate for certain functions will be required to demonstrate meaningful use of EHRs. For example, it will likely be necessary to document which functions (e.g. Computerized Physician Order Entry (CPOE), Eprescribing, Problem List, etc.) are used by clinicians. In addition, we expect that the level of adoption or extent of utilization of each functionality by each physician will be required. For example, determining if a physicians uses CPOE will not be sufficient, but reporting the extent of this use by providing the percentage of patients that orders entered via CPOE will likely be required.

To date, the method of choice for measuring EHR adoption has been by survey of EHR users. While surveys have their advantages, they also have the disadvantage of being periodic in nature, subjective, and somewhat intrusive. Alternative methods to track adoption of EHR systems were carried out during early implementations of our ambulatory EHR at Intermountain Healthcare. It was found that accessing the EHR transaction logs and data repository provided data that correlated to system usage [5]. Using this new automated source of information, adoption rates could be tracked continuously. For example, the number of physicians entering medication orders per day could be tracked on a daily basis or rolled up by month as shown in Figure 1. These computer tracking methods were shown to have certain strengths. For example, the data were objective and comprehensive, were available on a continual and often immediate basis, extraction of the data was inexpensive, and the data were relatively easy to collect and analyze.

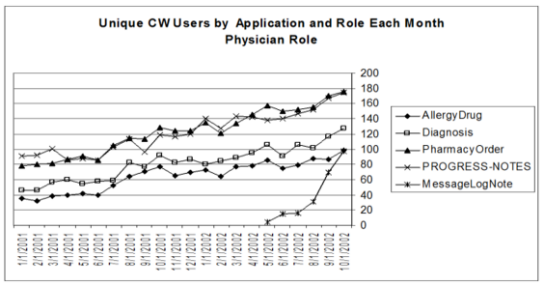

Figure 1- Early example of EHR Adoption Chart showing growth in users by month and by function (Orders, Messaging, etc.). Our early EHR application was known as CW.

Early success with creating computerized, real-time adoption measurement tools from the EHR led to decisions to develop a more robust system to track adoption using data from the EHR. This included tracking usage patterns of different applications or functions of the EHR.

A Pubmed [6] literature search was performed for information on using audit information to measure EHR adoption. However, very little specific information could be found.

This paper describes the development and implementation of system based on EHR audit information to measure EHR adoption and core functional usage patterns.

Materials and Methods

This analysis was performed using the HELP2 Electronic Health Record at Intermountain Healthcare. Intermountain Healthcare is a not-for-profit integrated health care delivery network which operates 22 hospitals (128,000 admissions per year), employs over 700 physicians working in 170 ambulatory clinics (6,023,000 patient visits per year), and insures approximately 500,000 individuals.

Intermountain's clinical information systems are relatively extensive and have been described previously [7]. Inpatient and outpatient data are interfaced to a longitudinal patient record and stored in the Clinical Data Repository (CDR) [8], the underlying repository for HELP2. Providers access different HELP2 modules for different functionality, including documentation of progress notes, problem lists, medication orders, etc. HELP2, has been in use with periodic updates since 1996. Over 13,000 clinicians use the HELP2 EHR each month to access the records of 258,000 unique patients.

Auditing capabilities are advanced and built into the foundation of HELP2 and the CDR. The purpose of the audit tables is to record the actions of users accessing various forms of patient data. For each encounter table, a corresponding audit table keeps a complete record of all transactions to provide an audit trail. Every time a table is updated, the system makes a copy of the new entry, adds the data elements needed for the audit entry, and moves the copy into a duplicate table reserved for audit purposes only. For instance, each time the main encounter table is modified, the corresponding audit table grows by one row. However, the main encounter table contains only the current data for each encounter.

Audit Data Mart

Early versions of computerized EHR adoption tracking of HELP2 pulled transaction data directly from the production data base, usually during off-peak hours so performance of HELP2 would not be impacted. As usage of the EHR grew, along with the demand for adoption metrics, it was no longer feasible to access the production system for adoption metric data. Preliminary analysis of audit logs showed that the data might be suitable for adoption metrics.

Coincidentally, Intermountain Healthcare's compliance department had designed a small system called the Compliance Audit Database (see Figure 2) that aggregated audit information from the CDR to provide reporting functions without impacting production systems. These reports identified users that accessed patient records in the event inappropriate access was reported or suspected.

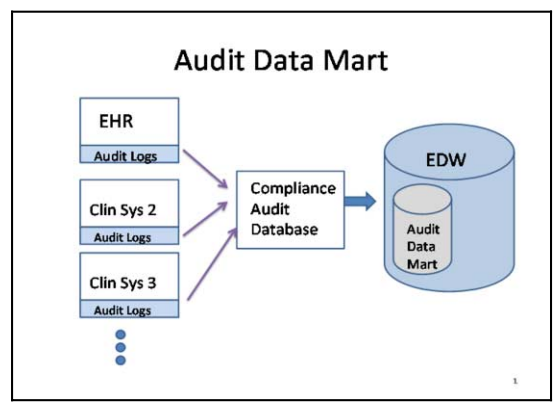

Figure 2- Flow of data from the EHR audit logs to the Audit Data Mart within the Enterprise Data Warehouse and

Early adoption metrics were pulled from the Compliance Audit Database. However accessing audit data from the Compliance Audit Database was problematic for several reasons. The audit data was abstract, and audit table analysts were often necessary to help create meaningful queries. Also, accessing aggregated data across multiple patients was very time consuming as the tables were not indexed ideally for the type of analysis necessary for EHR adoption reporting. There were also security and privacy concerns about accessing audit tables directly because the audit tables were not themselves audited.

To solve these issues an Audit Data Mart (See Figure 2.) was designed with the following goals in mind. Appropriate audit data, scrubbed of unnecessary sensitive information would be loaded from the EHR audit tables or the Compliance Audit Database into data mart tables in the Enterprise Data Warehouse (EDW).

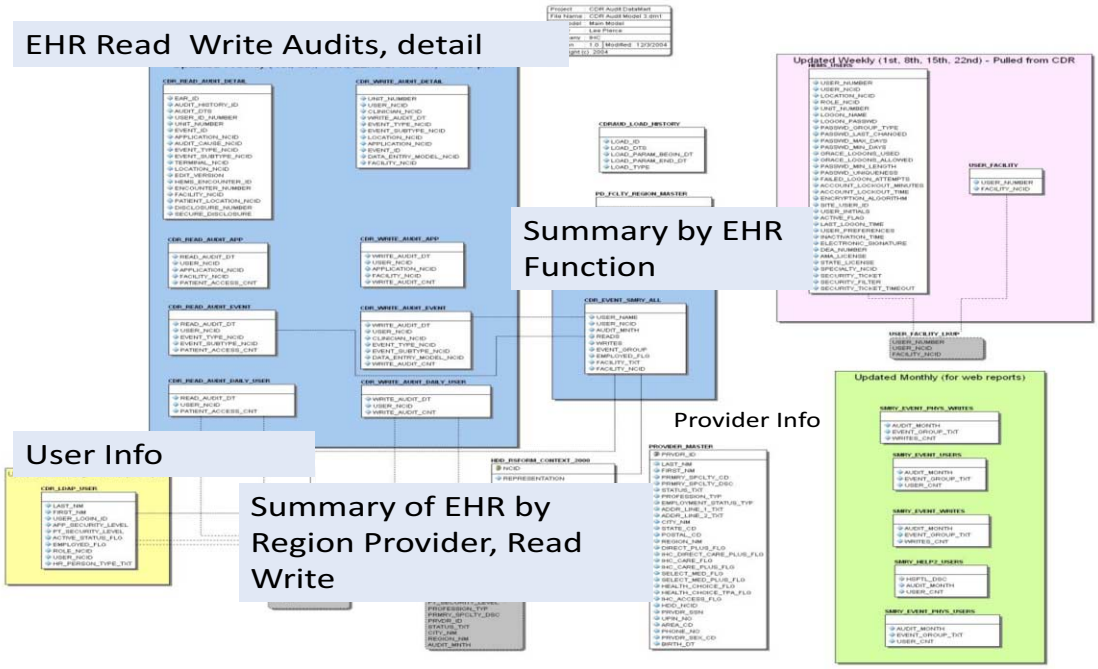

Figure 3 - Entity Relationship Diagrams of Audit Data Mart

Tables would be indexed and optimized for analysis and easy to search. Metadata would be used to describe the content, so analysts can pull data efficiently. Help2 user identification information would be linked to a common user identification scheme, to eliminate the need to match users from other clinical systems. Access to these tables would be audited in the Enterprise Data Warehouse to enable monitoring for security purposes. Access to the audit data mart would be managed by a data steward, and follows access guidelines outlined by Intermountain Healthcare.

The Audit Data Mart can be divided into 4 groups of tables, as shown in Figure 3. EHR Detail Read and Write Audit tables includes detailed information about read and write audits, including patient unit number, application type, data type, etc. User Info is data about the EHR user including name, employment location, role, etc. Provider information includes information about clinicians, including specialty, location, affiliation, etc. Finally, the summary tables aggregate common information into single tables. For example, User name, count of reads and writes per month, role, EHR application or function, etc. Audit data prior to the year 2000 are maintained, so historical reports and trending can be accomplished. The Audit Data Mart can be accessed with SQL or a similar query language tool. The tables are well defined in the metadata of the EDW. Reports can be easily built to answer many EHR adoption questions.

Results

The Audit Data Mart was queried to determine which EHR functions were used most frequently to access patient information for each department within Intermountain Healthcare. Usage of HELP2 EHR functionality was identified for all 836 Intermountain Departments, within 21 hospitals and 160 clinics. The results for the top 25 Departments are shown in Figure 4. The departments are shown in descending order of EHR use. The EHR high-level functions listed include Problems, Notes, Messages, Notifications, etc. This analysis shows the UV218 Emergency Room that the highest HELP2 usage, accessing over 20,000 unique patient records in 90 days, followed by Dixie Clinic and an Internal Medicine clinic, all based within the enterprise. Functions used to access the data include the ED System module, Problem Module, Notes Module, Encounters Module, Allergies Module, etc. This analysis also shows the different patterns of EHR function usage. For example, problem list was accessed on more patients in Dixie Clinic than anywhere else.

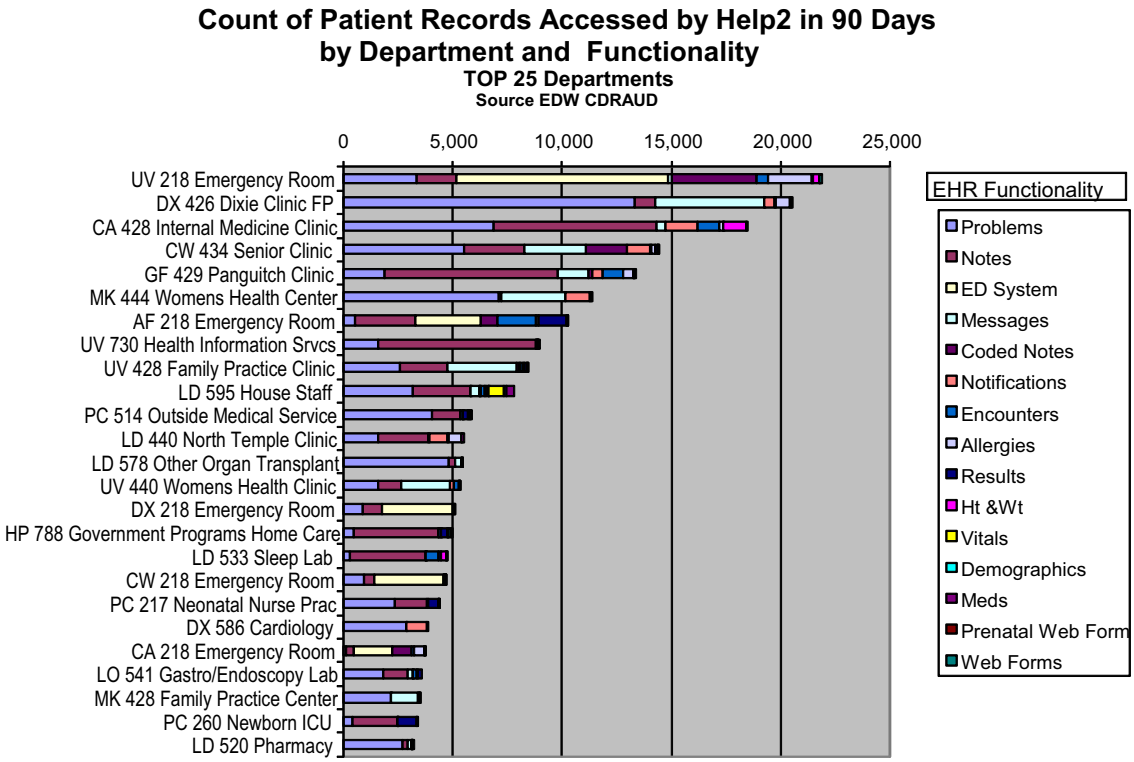

Figure 4 - Count of Patient Records by Department and EHR Functionality

Discussion

Early work on EHR adoption assumed a more or less homogenous adoption model, i.e. that all EHR users accessed the same functionality. Recently research has shown that EHR adoption can be more heterogeneous with users accessing different functions within the EHR [9].

For example, some users adopt more modules and use these modules on more patients. This has been our experience at Intermountain Healthcare [10-12]. Figure 4 shows the different types of EHR use within the top 25 departments. For example, Dx426 Dixie Clinic accessed problems list items on more patients than the UV218 Emergency Room. We have found that adoption metrics from the Audit Data Mart have been critical for tracking EHR implementations at Intermountain. For example, knowing the differing use of Problem List at two sites could trigger an analysis to identify the cause of the low usage. Often, more EHR training is necessary to improve usage of certain modules.

This analysis primarily took advantage of the 'Read Audit' data from the Audit Data Mart, which stores information about how clinical data is accessed. 'Write Audit' data, contains detail about how clinical information is stored. We have used the Write Audit data to identify which modules clinicians use to enter data into the EHR. We expect the 'Write Audit' data to be play a key role in documenting meaningful use of the EHR. For example, we can track which physicians enter CPOE orders, Eprescribing orders, allergies, etc.

The richness and ease of use of the audit data mart has resulted in the ability to rapidly measure EHR usage on a broad scale. In addition, it is easy to customize the reports to meet the needs of various stakeholders. For instance, detailed reports on individual users use of EHR functionality can be done for department use, or high-level summary reports can be run for the entire enterprise. These reports have proven to be useful in strategic planning [10], in tracking progress of current EHR implementations with our employed and non-employed physicians. We foresee this methodology being critical to support the documentation of 'meaningful use' of EHR functionality required by the ARRA incentive laws.

Limitations

There are limitations to using Audit repository data to measure system usage. Audit repository data was not designed to be used for measuring EHR adoption. Understanding the audit

table update process is key to transforming the audit table date into information that can be used for tracking EHR adoptions and functional use. For example, audits of some Help2 module screens such as Clinical Notes Review produce a row in the audit table for each clinical note summary that is shown on the screen. If 25 notes are shown to a user, there are 25 audit table rows written to that audit table. For adoptions and usage metrics, this detail is overkill. One method of managing this is to count only the first 'read' event per patient , per user, per module, instead of counting all 25. What is important is defining the methods of managing the information. We store these transformations in the metadata associated with the Audit Data Mart.

We have found other limitations to using the audit data. For example, some data is just not collected by the audit system. For example, the audit data mart and HELP2 audit data do not contain terminal-specific location information. Therefore, it was not possible to attribute events to a specific terminal or facility. To identify the location of Read Events and Write Events, users must be linked to the location identified by their human resource employment record.

Validation of Audit results

Validating the audit data mart data is critical to success. We shared our adoption metric results with a small sample of departments in order to make sure that our results made sense. We interviewed individual users and asked them which EHR functions they used, and to what extent. In each case the departments' feedback indicated that the audit data mart reports accurately represented their behavior and EHR usage.

Conclusion

This paper describes a method of EHR adoption measurement which capitalizes on audit logs, which are often common components of modern EHRs. This method has been used successfully at Intermountain Healthcare, a large integrated delivery network, to identify EHR usage patterns by functionality within the enterprise. This methodology will likely play a key role in documentation of 'meaningful use' of EHR functionality required by the ARRA EHR incentive laws.

A Scheme for Assuring Lifelong Readability in Computer Based Medical Records

Yasushi Matsumura[a], Noriyuki Kurabayashi[b], Tetsuya Iwasaki[b], Shuichi Sugaya[b], Kanayo Ueda[a], Takahiro Mineno[a], Hiroshi Takeda[a]

[a] *Department of Medical Informatics, Osaka University Hospital, Osaka, Japan*
[b] *Medical Information System Business Development Office, Solutions Group, Fuji Xerox Co., Ltd., Tokyo, Japan*

Abstract

Medical records must be kept over an extended period of time, meanwhile computer based medical records are renewed every 5 -6 years. Readability of medical records must be assured even though the systems are renewed by different vendors. To achieve this, we proposed a method called DACS, in which a medical record is considered as an aggregation of documents. A Document generated by a system is transformed to a format read by free software such as PDF, which is transferred with the document meta-information and important data written on the XML to the Document Deliverer. It stores these data into the Document Archiver, the Document Sharing Server and the Data Warehouse (DWH). We developed the Matrix View which shows documents in chronological order, and the Tree View showing documents in class tree structure. By this method all the documents can be integrated and be viewed by a single viewer. This helps users figure out patient history and find a document being sought. In addition, documents' data can be shared among systems and analyzed by DWH. Most importantly DACS can assure the lifelong readability of medical records.

Keywords:

Medical record system, Hospital information system, Information storage and retrieval

Introduction

Electronic medical record systems (EMR) have come into practical use. EMR is more convenient than paper based medical records because the carrying of paper files of medical records becomes unnecessary, and accessibility to medical records is greatly improved. A medical record is a record of observations and process of treatments of a patient. In Japan, there is a legal obligation to keep medical records for at least 5 years after the patients' treatment has ended. Some patients have been treated in a hospital for more than 20 years. Thus their medical records must be kept for an extended period of time. On the other hand, EMR has to be renewed every 5 to 6 years. On system renewal, not only hardware but also OS and application software are renewed. An EMR is composed of several systems provided by different vendors, especially in a large hospital. These systems may have to be renewed by different vendors due to changing needs of hospital staffs. In this circumstance, in order that the data stored into the system can be viewed persistently, it must be stored by a consistent well-considered method. Otherwise, when the application software is renewed, the data stored in the old system cannot be viewed. EMR already started without much consideration for the long-term readability of medical records.

To solve this problem, we propose a document based electronic medical record, considering a medical record as an aggregation of documents. A document's information consists of the document body and its meta-information. The data form of the document body is transformed into PDF, JPEG, TIFF or DocuWorks, etc. which can be read by free software universally available. Documents' meta-information is collected in a unified format. In the field of medical imaging, the concept of PACS (Picture Archiving and Communication System) is well-known and widely used. In PACS, image data composed of image body data and its meta-information is managed uniformly, so any images can be viewed by a single viewer. Our proposed system is similar to PACS where documents are substituted for images. Thus we name this system DACS (Document Archiving and Communication System).

By collecting all the documents of a patient, it is possible to view them by a single viewer. In the existing EMR, patients' clinical data are stored in different systems. Each system sets up a web system to let users view it from the patient's clinical record view window. By this method it is possible to access a requested document. However, it is difficult to comprehend a patient's entire clinical history, because different kinds of needed documents can be accessed only from their own window. Hospital staff needs to comprehend a patient's problems and requirements in a short period of time when they participate in the patient's medical care. In this case, they need to know what kind of documents exists for the patient. In addition, they have to view related documents with the one

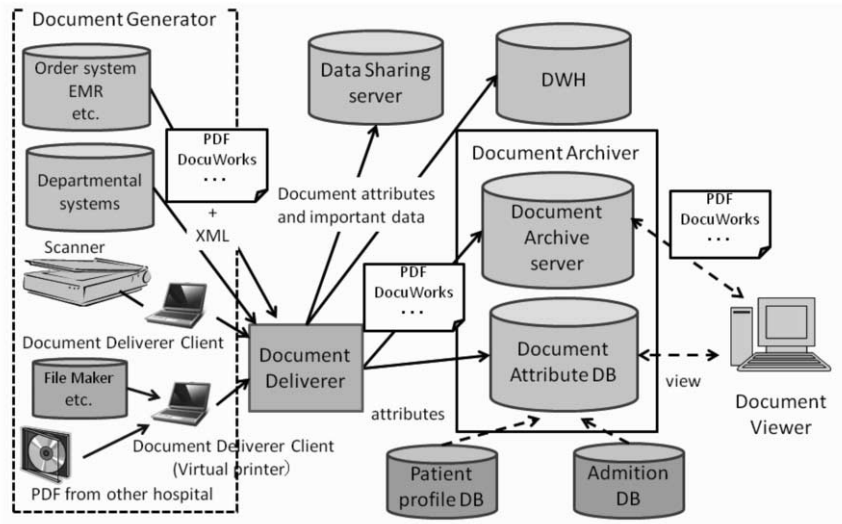

Figure 1- Basic configuration of DACS

currently being viewed, even though they are generated by different systems.

If medical record data is handled by documents, a worry arises that the data in the documents might be difficult to process. This data is sometimes required to be shared among different systems. There is also a request that the data in the documents be used for analysis. To fulfill these requirements, we proposed a method for collecting important data in a document with document's meta-information.

Methods

Fundamental Concept of DACS

In DACS, medical records are handled as an aggregation of documents instead of data. Typical document types are examination reports, operation records and discharge summaries which are created for respective events. In addition, chronologically continuous data is converted into a series of documents by setting an intersection. For example, a progress note that is written continuously for an inpatient is divided by day and by the department of the creator into a series of documents.

The basic configuration of DACS is shown in Fig.1. Systems that generate documents are called Document Generators. All the generated documents are transferred to a Document Deliverer. Next, the Document Deliverer transfers them to the Document Archiver, the Data Sharing Server, and the Data Warehouse (DWH). The Document Viewer, which runs on each EMR terminal, accesses Document Archiver to display documents.

Document Body and its Attributes

A Document generated by a system is transformed to a standard format read by free software. In our DACS implementation, PDF, JPEG, TIFF or DocuWorks are used for said format. Document information is separated into a document body for readability and its meta-information.

Document meta-information consists of document attributes. The mandatory attributes are patient ID, document class code, event date, and department code. Document class code is unique to each document class in a hospital. The document class is defined by the smallest granularity. They are grouped into super-classes by the external table file, because a classification scheme varies according to the requirements of the subsystems.

Event date is the date most appropriate for the document. For example, the event date of an examination report is the date on which the examination took place rather than the date on which it was created. Documents such as discharge summaries and flow-sheets are records of a certain period of time. For these documents, attributes for the start date and end date are provided. In case two or more documents of the same class were created for the same patient on the same date, the documents need to be identified by time. So time attribute is also provided.

A document sometimes has several departments as an attribute, such as the department that placed the order, that created the document, or where the patient was hospitalized. A suitable one is selected for each document class.

In addition to the aforesaid mandatory attributes, a numbers of optional attributes are defined. The patient profile information, such as patients' names, can be retrieved from the system through patient ID. Although there is important information

such as class of inpatient/outpatient or document's author information, some of the latter are practically unavailable due to documents' origin. So we did not make them mandatory. We limited the mandatory attributes to those required for the Document Viewer to be described shortly.

In order to share with other systems important data included in a document, and use it for data analysis, such data is extracted from a document. The data is presented by item code, item name, value name and value code if it exists. The item code must be assigned uniquely in a document class. Thus uniqueness of an item can be ascertained by the item code along with the document class code.

These documents' attributes and important data in the documents are conveyed by the XML format.

Transferring Documents from Document Generators

There are 4 types of Document Generators. 1) Physician order entry system, EMR, etc. 2) departmental system 3) document scanners 4) virtual printers.

Types-1 and 2 are intersystem connection type and are essentially the same. In most settings, printed output image is available, so the image is converted into PDF format and the document's meta-information is embedded in the prescribed XML format when it is sent to the Document Deliverer.

Intersystem connection in Type-2 is typically a transmission of a report. An originating system generates a PDF file from a print output image, and an XML file including the document's meta-information. Then it transmits them to the Document Deliverer when the report is approved.

In Type-3, a scanned image is transformed to DocuWorks format. Because QR code is printed on sheets, the document's meta-information can be recognized by reading it. This DocuWorks file and the XML file including the document's meta-information are transmitted to the Document Deliverer. We call this module a Document Deliverer Client. Documents are then transmitted to the Document Archiver and digitally signed and time-stamped using XAdES [1].

The virtual printing system of Type-4 is similar to Type-3. When the virtual printer outputs a print image using its driver, a DocuWorks file is transferred to the Document Deliverer Client. In case patient ID, event date, and document class ID are set at predefined positions in header and footer of an output document, they can be read automatically. In case these data are not set, they are input manually. In Types-3 and 4, a DocuWorks file together with a prescribed XML file is transmitted to the Document Deliverer from the Document Deliverer Client.

Delivering Documents

The Document Deliverer performs the task of delivering documents received from Document Generators. The Document Deliverer lightens the load of Document Generators for document archiving. FTP, CIFS and SOAP are available protocols for transferring document information from Document Generators to the Document Deliverer. Although bidirectional communication over SOAP is reliable, most developers prefer FTP because it is easy to implement. The Document Deliverer receives a document body file and its meta-information in the XML. It registers the document body and its meta-information to the Document Archiver. The Document Deliverer also delivers the data received to the Data Sharing Server and to the DWH. Compared to the method in which each Document Generator directly sends document information to the Document Archiver, the Data Sharing Server and the DWH, data transmission via Document Deliverer greatly reduces the load of Document Generators.

Preserving Documents

Document body and document attributes are stored into the different databases in the Document Archiver. No medical specialization is needed for the server in charge of the document body. Here we employed a Document Management System (DMS) product from Fuji Xerox. On the other hand, for the database for document attributes medical specializations are necessary. This database is needed for the Document Viewer. Besides information received from the Document Deliverer, patient profile information and admission history are also necessary. These are obtained from the hospital information system.

Viewing Documents

There are two ways for viewing documents. One is focusing on a patient to view various documents of that patient, and the other is focusing on a document type to view the documents of patients. The former is the prerequisite for EMR, while the latter is a function required for department operation. We call these viewers Medical Record Viewer and Register Viewer, respectively.

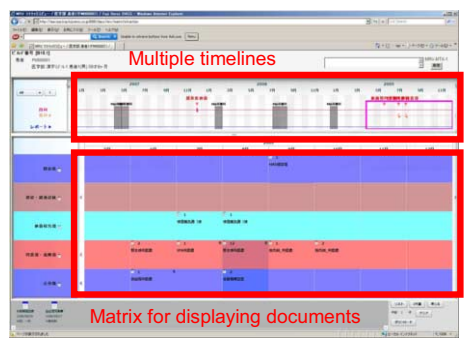

Figure 2- Matrix View

A Medical Record Viewer has two types of viewers: Matrix View which shows documents in chronological structure, and Tree View showing documents in class tree structure. The Matrix View (Fig.2) is designed to overview the patient's medical history with information over half a decade shown on one screen. Multiple timelines are displayed in the upper pane. Patient encounters (creation of progress notes) in each department and examinations carried out for the patient (submission of examination reports) are marked on timelines. Hospital admissions and important event such as operations are also dis-

played. Documents in the area specified by a thick frame on the timeline pane are browsed at the lower pane. The lower pane displays the documents in matrix form. Rows correspond to document classes and columns indicate periods. Because many document classes exist even in one patient, all the items presented in rows cannot be seen without scrolling. So we design a method to accomplish this. In this method, the thickness of the layer changes flexibly according to presence of documents. Because many documents are rarely generated on a same day, most of them can be viewed without scrolling.

When a document is designated in this pane, a browsing window called Focus View (Figure 3) is opened to display the content. The Focus View is set double-screen as default.

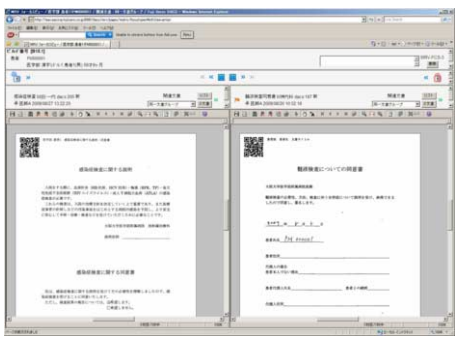

Figure 3- Focus View

Tree View is designed for searching a document. The document to be searched can be accessed according to date, document class, inpatient or outpatient by tracing classification folders.

Register Viewer is a viewer meant to read through documents in a specified class. It needs access control. For example, doctors in charge can access all the documents generated by their department. On the other hand, they cannot see the documents generated by other departments as a whole. Additionally, the hospital staff who engage in a special work for patients should be permitted to access the documents created by the staff. For example, the technician in charge of echocardiography should be able to view all the echocardiography reports. However, other hospital staff should not be permitted to access this view.

Printing Documents

Fuji Xerox's DMS has the function of outputting all the files of a patient for a designated period to a predefined directory. Numbers representing orders for print are set in the filename of the output files so that the print module can print them in a predetermined order.

Shared Database and DWH

By storing data in the Data Sharing Server, the data can be shared among different systems. In spite of the variety of data types, all the data can be stored in the scheme of item code, item name, value name and value code with the originated document's attributes such as patient ID, document class code, and event date. In this data scheme, one value is saved in one record. The primary key of the database file is a composition of the document class code and the item code. By linking with the table where the primary key corresponds to a concept code, items originated from different documents with the same concept code can be recognized as the same item. When no data in a document are set in the XML format, a fixed data is stored in the item code field in order to store the document's attributes.

The data scheme of DWH is the same as that of the Data Sharing Sever. Because not all of the important data is shared among systems, The Data Sharing Server keeps the limited items for few months in order to keep good response time. DWH, on the other hand, keeps all the important data and document's attributes sent from every Generator.

Results

We are now preparing for the renewal of the hospital information system of Osaka University Hospital which is going to start in January, 2010. It includes various types of physician order entry systems, medical record entries such as initial visit reports, progress notes, discharge summaries, etc. which are produced by NEC. In addition, there are many special departmental systems which are produced by different vendors. DACS is implemented in this new system. Most of the system is already in place. All of the clinical documents generated by various types of systems except for laboratory test results can be collected in the Document Archiver. For each Document Generator, to send documents by the proposed method, a program module for it had to be made. This method was so simple that all the systems in our hospital could make it. There were some systems that could not be customized. For these systems, the method of virtual printer was effective.

There are some paper based documents which originally cannot be digitalized. These documents also have to be collected for management by paperless computer based medical record. For these documents, scanning is practical and effective [2]. After scanning the document data are handled in the same manner.

Because all the documents are collected into the Document Archiver, they can be viewed by a single viewer. The Matrix View that we developed in this project is distinctive. The timelines of the Matrix View on which a constellation of clinical events marked will help users comprehend the trend of the patient's history by pattern recognition. The Focus View which is for seeing a document's contents has two screens. Thus the present one can be compared with the past one in the same document class. It can also view a discharge summary concurrently with examination reports during the same hospital admission.

Medical records are sometimes demanded for disclosure. In case of a lawsuit, all the medical records must be printed out for preservation of evidence. If some of them are missing, it may be regarded as concealing evidence. It is impossible for the EMR that integrates documents by web systems to print them out in readable order. Furthermore users can easily neglect to print out some part of the record. Because DACS ag-

lect to print out some part of the record. Because DACS aggregates all the documents, it is easy to print out all the records in a designated order without omitting anything.

Even though DACS is document based, important data in documents can be shared among different systems and be analyzed by DWH. We selected the data which may be used by other systems or be analyzed for clinical research in each document class. The requirement of our method is only to assure uniqueness of item code in each document. The vendors which develop the systems (Document Generators) can easily comply with this requirement and embedded them in the XML format.

The most essential point of DACS is to assure lifelong readability of medical record. Because the documents' bodies are viewable by free software, it will be read over a long period of time. Furthermore the structure of the document's meta-information is so simple that conversion of the data stored in a DACS to another new system is not difficult. Thus documents stored in a DACS will able to be viewed continuously.

Discussion

The scheme for securing lifelong readability of medical records is fundamental for management by paperless computer based medical records [3]. A medical record can be considered as an aggregation of documents. The essence of our method is that the document's body data is transformed into data forms which can be read by free software universally available and is collected with the document's meta-information.

For exchange of documents between systems, CDA (Clinical Document Architecture) is often used [4]. CDA is expected to be foundational for the realization of semantic interoperability for clinical statement. Our proposed method also uses XML as a conveyer of documents' meta-information, which corresponds to CDA header. Thus our method corresponds to a use case of CDA level-1 using external files. In order to share and analyze data, important data is also conveyed by the XML format. In CDA, data about patient is written in entry element in the part of the document body where code should be assigned as OID. In our method, the item code is simply required to be unique in a hospital. The concept code is assigned when the XML format is received by the Data Sharing Server or the DWH. That is because CDA aims at data exchange between facilities, code system used in CDA should be clearly demonstrated in the document. On the other hand, our method aims data exchange within a single facility. Thus it is easier to assign codes systematically after receiving a document. If the method for sending a document is complicated, it is difficult to collect all the clinical documents in a hospital. The XML format of our method is so simple that any system can easily generate it. It is speculated that it will take time for CDA to become widespread. Before that, our method is a practical solution.

Because DACS aggregates all the clinical documents, it enables users to view them concurrently even though the documents are generated by different systems. In paper based medical records, files for patients are separated according to inpatient or outpatient status. In computer based medical records, all the records for a patient can be viewed without decoupling. However, sometimes there is a lot of information even on one patient. We developed a document viewer system which automatically arranges clinical documents to help users figure out a patient's history and find a needed document.

The hospital information system of Osaka University Hospital consists of several server computers and more than 2000 PCs, which are connected by 1 Gbps network. On this hardware, physician order entry systems, document creating systems, a reservation system, PACS, various types of departmental systems, an accounting system, a physical distribution system, etc. are running. DACS is one of these applications. A hospital information system in a large hospital usually consists of many systems produced by different vendors. A hospital information system can be operated as EMR without DACS by showing clinical information by using web system. However, in order to integrate various types of systems that generate clinical documents, DACS is desirable. Furthermore, to secure medical record readability over an extended period of time, we had found our DACS method to be most practical.

Abstract

Due to the fact that health care professionals in Malawi are often overstretched, the use and quality of health data can be compromised. The Malawi Health Management Information System (HMIS) has streamlined data collection and reporting and increased the use of data to improve care. Obstacles remain, including incomplete reporting and low staff morale. With the Baobab Health Trust and the Malawi Ministry of Health, Partners In Health piloted an innovative point-of-care data system for primary care that functions alongside OpenMRS, an open source medical record platform. The system has given access to a patient-level primary care dataset in real time. Initial results highlight some of the benefits of a point-of-care system such as improved data quality, emphasize the importance of sharing data with clinical practitioners, and shed light on how this approach could strengthen HMIS.

Keywords:

Point-of-care systems, Primary health care, Malawi

Introduction

Background

The convergence of falling information technology costs, improved computer literacy and greater availability of open source software platforms has increased access to electronic medical record systems in resource-poor settings. Early successes in some locations include timely delivery of lab results, tracking of drug supplies [1] and easier aggregate reporting [2]. The potential to improve patient care through better compliance with standardized guidelines, clinical decision support and other measures is promising. While such initiatives are in early stages with less documented successes, a preliminary evaluation of the Malawi Ministry of Health's (MOH) use of an electronic data system for antiretroviral therapy suggests the results are positive [3].

Malawi has poor health and economic indicators relative to other countries in Southern Africa and the world in general. In 2005, 41.7% of a population of 12,884,000 lived below the poverty line. The life expectancy at birth was 41 for both males and females, compared with averages of 47 and 49, respectively, in nearby countries [4].

Human resources in Malawi's health sector are scarce. A 1998 estimate indicated that 36.3% of physician posts and 18.4% of nurse and/or midwife posts were vacant [5]. As of 2002 the coverage rate of physicians and nurses per 1,000 patients was 0.022 and 0.589, respectively, compared with averages of 0.217 and 1.172 in other nearby countries [4]. Staffing shortages have resulted in increased reliance on health professionals with only two or three years of training [6], and task-shifting of some activities, such as data capturing, to staff with little or no formal training [7].

In 1999, the health information system in Malawi was restructured into a new Health Management Information System (HMIS), with the goal of overcoming the lack of reliable data and inadequate use of data in healthcare planning. A small set of indicators was chosen to minimize the burden of data collection. The system was primarily paper-based, including client health booklets, facility-based registers, data aggregation and monitoring workbooks and annual planning and review tools [2]. District-level HMIS Coordinators entered data into an electronic system which was then aggregated at a central level. As of 2002, facility-level information was available on a monthly basis for the first time. Obstacles remain in spite of the successes, including [2]:

- inadequate reporting from some facilities,
- staffing shortages for qualified personnel,
- data aggregation by clerks with little formal training [7],
- low motivation of HMIS personnel,
- insufficient data use at the local level, and
- low data use where quality is perceived to be poor [7].

Partners In Health (PIH) began a partnership with the Malawi MOH in early 2007 in rural Neno District. Building on its experience in Rwanda, Lesotho and elsewhere, PIH implemented OpenMRS, an open source electronic medical record system designed to support the delivery of healthcare in developing countries [8], by collecting HIV and TB data. PIH

saw potential in the Baobab ART system (BART), a point-of-care electronic data system developed by the Baobab Health Trust [9], but this system was not fully compatible with OpenMRS. Primary care data collection was not a part of PIH's initial electronic medical record system, so data from HMIS had to be relied upon.

Goal

To address some of the shortcomings of the HMIS dataset and improve access to data at the point of care, PIH sought to work with the Baobab Health Trust to develop a point-of-care data collection system for primary care. It would be based on the Baobab ART system (BART) and be fully compatible with OpenMRS. It should improve the quality of patient-clinician interactions and increase the use of the data for planning purposes in Neno District. It was also hoped that collecting this dataset at the point of care could demonstrate the feasibility of the approach in addressing some of the challenges affecting HMIS. Finally, the integration could pave the way for a full integration of BART with OpenMRS, bringing the benefits of the OpenMRS community [10] to existing Baobab implementations.

Challenges

Internet access is very important to the development and piloting of a new electronic medical record system, but connectivity from local Internet Service Providers (ISPs) was not available in Neno District. Finding an alternative source for Internet connectivity was key to PIH's operations as a whole and the development of its electronic medical record systems in particular.

Power supply in Malawi is unreliable. While most of the health facilities in Neno District are connected to the grid, power outages ranging from a few hours to an entire working day are common. Utility line power surges are a problem, as are lightning strikes. A point-of-care electronic data system must work when the power is off for long periods of time and must be resistant to power surges and lightning strikes.

To keep costs low and reduce downtime, equipment for the point-of-care system would need to be low cost, easy to use, and reliable. It should fit smoothly within the existing workflows of the hospital. Given the power issues mentioned above, the equipment should have low power consumption. A reliable supply chain for IT hardware and consumables, such as printer labels, must also be established.

Integrating BART and OpenMRS also required a technical solution. The OpenMRS application is programmed in Java and runs on the Apache Tomcat web server with a MySQL database [8]. PIH started its implementation in Malawi at version 1.3 of OpenMRS, and has since migrated to version 1.4.4. BART is programmed in Ruby on Rails and uses version 1.0.18 of the OpenMRS data model, making it incompatible with the OpenMRS implementation used by PIH. Due to the different programming languages of the applications, integration was not trivial.

Inconsistent spellings of names and addresses are common in the HMIS dataset. To avoid unnecessary patient duplication, the system needed an easy way to find a patient record, and an ability to compare slightly different spellings of a name. Data validation would be crucial to avoid common entry errors.

With high patient loads and overstretched staff, the system would need to be as easy-to-use as possible. Given that most staff at the hospital were not familiar with computers, it would need to be intuitive in order to require a minimal amount of training. Time-saving measures would have to be adapted wherever possible, and the new processes would need to be easily integrated into existing workflows. To encourage adoption and consistent use of the system, it would need to be immediately useful to clinicians while also providing a perceived benefit to the local MOH management team.

Materials and Methods

Hardware and power

PIH purchased a VSAT Internet connection for its program activities in Neno District Hospital but could not install connections at other sites due to the high cost. The Internet network was extended around the hospital with low-cost wireless technology, but the rugged topography of Neno District prevented point-to-point connections between the hospital and any of the other health centers in the district. Faced with these connectivity limitations, PIH decided to pilot the point-of-care system exclusively at Neno District Hospital.

PIH benefited from advances in the implementation of BART in addressing power problems. Four 12-volt deep cycle batteries in series provided backup power. A 48V, 10 Amp charger was protected from voltage spikes by a surge arrestor. The system was connected to the main building ground to prevent surges and lightning strikes from damaging the equipment. A Low Voltage Disconnect (LVD) device was installed after the batteries and the load to prevent them from being drained too low, preserving their lifespan. As a sum of its parts, the system functioned like a large online uninterruptible power supply. The computer and network hardware chosen were generally low-power DC equipment to enhance the battery life.

Table 1 - Summary of power supply equipment

Item	Number	Unit	Total
13A Surge Arrestor	1	$70	$70
10A 48VDC Charger	1	$133	$133
102 Ah 12V Battery	4	$200	$800
48V LVD	1	$160	$160
Total			**$1,163**

PIH also utilized the experience of Baobab in the selection of hardware. The data collection devices were low-power (13 Watts) thin client touchscreen computers modified by Baobab receiving Power Over Ethernet (POE) from a special network switch wired to the batteries. The thin-client approach precluded potential problems of computer viruses. A label printer was used to print a unique patient identifier as a barcode and summaries of encounters for the patient passports. A barcode scanner was used to quickly find patient records. The printer was powered directly off of the batteries, and used rolls of

labels and thermal transfer ink ribbon. The application and OpenMRS were installed on a single low-powered server (30W idle, 60W peak load).

Table 2 - Summary of point-of-care equipment

Item	Number	Unit	Total
Baobab touchscreen	5	$400	$2,000
Barcode scanner	5	$60	$300
Thermal label printer	5	$410	$2,050
Custom POE power supply for printer	5	$100	$500
24 port POE switch	1	$375	$375
Linux server	1	$1,670	$1,670
Ethernet cabling	1	$200	$200
Total			**$7,095**

Table 3 - Summary of consumables purchased in first year

Item	Number	Unit	Total
Box of 12 label rolls	3	$310	$930
Box of 12 ink rolls	3	$60	$180
Total			**$1,110**

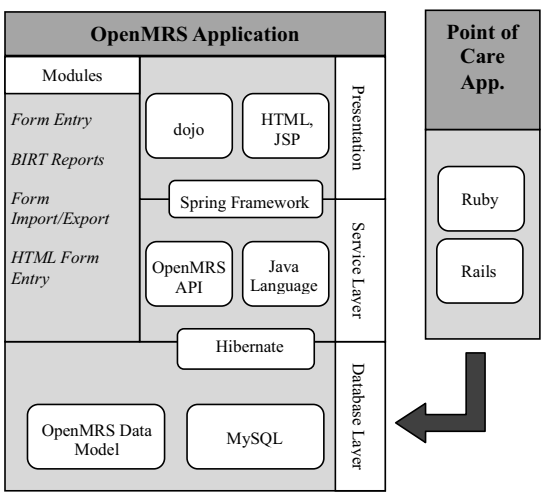

Figure 1 - Linking the OpenMRS web application with the new point-of-care system

Software

Options considered for integrating the Baobab technology with OpenMRS included working together at the database layer, using a java ruby bridge to allow the Baobab application to write to the OpenMRS Application Programming Interface (API) [8], or rewriting the entire application in Java. In the end the database layer was chosen for its simplicity and potential for adoption by Baobab at other sites (see Figure 1).

Patients sometimes need to be looked up by name if the passport is not available or the barcode is unreadable. To avoid patient duplication due to inconsistent spelling, a soundex algorithm was developed that matched similar sounding letters (eg, r's versus l's and c's versus k's), counted double letters as a single letter, and ignored vowels. Unlike classical soundex algorithms, the first letter was also accounted for, allowing names such as 'Kathleen' and 'Catherine' to be compared:

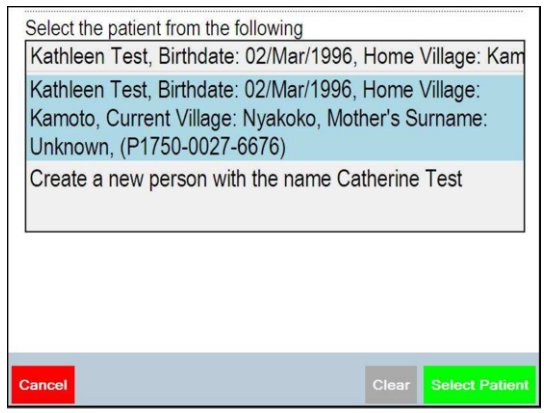

Figure 2 - Example results from soundex algorithm

The new system maintained conventions of the BART user interface designed to make it easy to use, displaying one question per screen and using large buttons to facilitate data entry.

Figure 3 - Example user interface

Data validation was also used where possible to prevent data entry errors (eg, unrealistic patient weights).

The data collected by the point-of-care system included basic demographics, height, weight, diagnoses and treatment prescribed, and was consistent with the data collected by HMIS. However, HMIS collects diagnosis data on a set of only 63 indicators and some broad definitions (eg, 'All other non-communicable diseases') are not conducive to a patient-level dataset. The new system allows clinicians to select from a list of more than 530 diagnoses allowing for explicit answers be-

fitting a patient-level dataset. In the future, these diagnoses will need to be mapped to the HMIS indicators and to an established coding system such as SNOMED.

Various time-saving measures were put in place. The system shows a list of common treatments for a particular diagnosis in order of frequency (see Figure 4). An encounter label can be printed, summarizing information entered electronically to avoid writing it out by hand. A patient summary screen displays recent information about the patient for easy reference. Reports were programmed using the Eclipse Business Intelligence Reporting Tool (BIRT) for the OpenMRS BIRT rendering module. These included a weekly summary of clinical activity and a summary for a single diagnosis including most common village (an epidemiological value), and most common treatment combinations (to address prescribing habits). These reports were delivered each Monday during the morning report at Neno District Hospital.

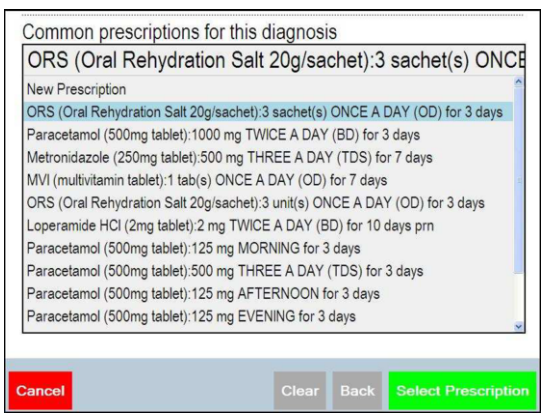

Figure 4 - Common prescriptions for gastroenteritis

The implementation of the point-of-care primary care system was done in a phased approach, allowing key elements of the process to be fine tuned (see Figure 5). Starting with patient registration in June 2008 allowed many of the hardware and networking issues to be worked out without impacting the clinical workflow and registered many patients before new data collection was added. Diagnosis was captured by clerks in September 2008 and by clinicians in January 2009. Capturing of treatment was added in May 2009 once the "suggested prescription" feature had been implemented. Weight and height were added in July 2009.

<table>

Figure 5 – Phased implementation of paper (p) and electronic (e) data capturing at Neno District Hospital

Results

Implementing a point-of-care data collection system at Neno District Hospital has given PIH and its MOH colleagues access to a rich set of data. Nationally-unique patient identifiers, (more than 1,000,000 of which have been issued at Baobab sites), have been assigned to patients at Neno District Hospital, and demographic information has been collected.

Table 4 - Summary of cumulative patient registrations at Neno District Hospital as of September 30th, 2009

Gender	Under 15	Over 15	Total
Male	5,171	5,942	11,113
Female	6,065	8,734	14,789
Total	11,236	14,676	25,912

The real time dataset is easier to make use of than the HMIS dataset. By integrating data entry into the point-of-care, data accuracy should increase due to reduced transcription. The collection of diagnoses and treatment information by clinicians also obviates the need to have staff with limited training and limited supervision enter the data.

Table 5 - Five most common diagnoses, January through September 2009

Diagnosis	Number	%
Upper respiratory tract infection	7,773	26
Malaria	7,608	25
Musculoskeletal pain	4,482	15
Dyspepsia	674	2
Gastroenteritis	658	2
Remaining diagnoses	9,057	30
Total	30,252	100

Producing a list of common treatments for a diagnosis helps save the clinicians' time and provides suggestions for reference in unfamiliar cases.

Table 6 - Top five most common treatment combinations, Upper Respiratory Tract Infection, September 2009

Treatment	Number	%
Paracetamol 1000mg TDS	98	18
Ibuprofen 400mg TDS	76	14
Chlorphenamine 4mg OD + Ibuprofen 400mg TDS	63	11
Paracetamol 1000mg TDS + Cotrimoxazole 2 tabs BD	37	7
Chlorphenmine 4mg BD + Ibuprofen 400mg TDS	28	5
Other treatment combinations	252	45
Total	554	100

The patient-level dataset is linked with electronic HIV and TB data, unlike the HMIS data. Retrospective data entry of patient-level data from HMIS registers is generally not practical due to difficulties in comprehending the handwritten text.

The power backup system continues to function during extended power outages. The first set of batteries installed lost their charge capacity in November 2008, but a Low Voltage Disconnect has prevented this problem from occurring again. The touchscreens occasionally have calibration issues, causing unresponsiveness. PIH does not have the capacity to correct this problem so the units have to be sent to Baobab to be fixed. A more reliable off-the-shelf solution with an extended warranty will be desirable.

Discussion

The biggest challenge to the new system has been its adoption by MOH clinical staff. Initially, minor technical problems might cause a clinician to stop using the system. Likewise, they were unlikely to use it if their patient loads were too high, and unplanned staff shortages are common. A series of focus group meetings helped to identify common problems and increased user confidence in the system. Equally important, the weekly reports have become popular with the local MOH management team. Their enthusiasm has trickled down to the clinicians using the system and has increased its use over time, as a comparison of patient registrations and diagnoses shows:

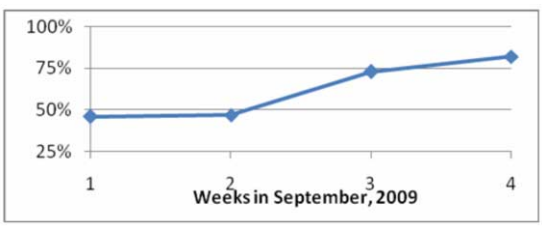

Figure 6 - Percent of patients registered electronically at Neno District Hospital with a diagnosis recorded

Not all of the patients who are seen at the registration desk visit an outpatient clinician, so the figures from the final two weeks of September in Figure 6 represent a high proportion of the patients who actually saw a clinician.

Conclusion

Malawi's Health Management Information System (HMIS) has provided decision makers at the district and central level with monthly access to facility-level data. Persistent problems such as a lack of qualified staff, low morale among data collectors and poor training and supervision among those responsible for aggregating the data have adversely affected data quality. Together with the Baobab Health Trust and the Malawi Ministry of Health (MOH), Partners In Health (PIH) has piloted an innovative electronic system for collecting primary care data at the point-of-care. Since clinicians creating the data are actively involved in capturing it, common data entry mistakes are reduced. The amount of time required to use the system has been minimized by integrating it into the general workflow of the clinic. Summary reports in OpenMRS have increased the overall use of the data and have had a positive effect on the use of the system as a whole. Political will on the part of MOH management will be essential if the system is to continue being adopted successfully. This early success highlights the potential for such an approach to address problems in the HMIS dataset and the general collection and use of medical data in resource-poor settings.

Abstract

The objective of this study was to determine the relative efficiency of novices compared to a prediction of skilled use when performing tasks using the touchscreen interface of an EMR developed in Malawi. We observed novice users performing touchscreen tasks and recorded timestamp data from their performances. Using a predictive human performance modeling tool, the authors predicted the skilled task performance time for each task. Efficiency and rates of error were evaluated with respect to user interface design. Nineteen participants performed 31 EMR tasks seven times for a total of 4,123 observed performances. We analyzed twelve representative tasks leaving 1,596 performances featuring six user interface designs. Mean novice performance time was significantly slower than mean predicted skilled performance time ($p < 0.001$). However, novices performed faster than the predicted skilled level in 208 (13%) of successful task performances. These findings suggest the user interface design supports a primary design goal of the EMR – to allow novice users to perform tasks efficiently and effectively.

Electronic medical records, Developing countries, Human computer interaction, Usability, Predictive human performance modeling

Introduction

Electronic Medical Records (EMRs) provide important benefits to healthcare delivery such as improving the quality of patient care, decreasing medical errors, and reducing costs [1-3]. In developing countries and low-resource settings we believe the potential of EMRs to improve patient care is magnified, given the utility of existing paper medical record systems. However, a combination of technical and socioeconomic challenges impedes the successful adoption of EMRs in these settings. The healthcare environment is characterized by a lack of a reliable infrastructure, large-scale health crises such as HIV/AIDS, and a health worker shortage [4]. An EMR implemented in this context must support the tasks of clinicians with no prior computing experience who endure poor working conditions and a high patient-to-clinician ratio. High rates of staff turnover further complicate the successful implementation of EMRs by increasing the number of new clinicians who need to learn to use a system efficiently and effectively.

Learnability and efficiency are two aspects of system usability that are critical factors for successful implementation of health information technology in developing countries. Learnability refers to the effectiveness with which a new user can perform tasks. Efficiency is the time required for a user to perform a task, given a design. Our long-term goal is to develop an EMR user interface that is both learnable and efficient for novices and experienced users alike in a developing country. The objective of this study was to evaluate the efficiency and learnability of an EMR designed to manage HIV/AIDS patient records in Malawi. In particular we wanted to measure the efficiency of the EMR for new users in comparison with the efficiency level that experienced users should be able to attain given a particular user interface design. As a first step towards evaluating the design, we used health sciences students at the University of Pittsburgh to represent novice EMR users with the intent to refine our evaluation with novice users in Malawi.

Baobab Anti-Retroviral Therapy (BART) EMR in Malawi

Malawi, like many countries in sub-Saharan Africa, is experiencing a devastating HIV/AIDS epidemic that has infected close to 1 million people, or about 8% of the population. Baobab Health Trust, a Malawian non-governmental organization, has partnered with Malawi's Ministry of Health to implement an EMR in six HIV/AIDS clinics to improve the delivery of care and support monitoring and evaluation of Anti-Retroviral Therapy (ART). Clinics using the Baobab ART (BART) EMR were providing free ART to 23,667 patients as of December, 2009. A core feature of the BART EMR is a Touchscreen Clinical Workstation (TCW) deployed at the point-of-care (Figure 1). The TCW is a low-cost information appliance that captures data during patient visits. TCWs support clinical decision-making by guiding health workers through patient en-

[1] Dr. Monaco is now with UPMC Health Plan, Pittsburgh, Pennsylvania.

counters consistent with national treatment protocols for ART [5, 6].

Baobab Health Trust has innovated hardware and software solutions to introduce point-of-care computing in low-resource settings. These innovations include alternative power approaches, adaptation of hardware to increase system reliability in environments with high humidity or dust, and large-button touchscreen user interfaces. The TCW user interfaces are wizard-like, presenting the user with a single question per screen (Figure 2). The constraints of the task and the setting – that is, a multistep, ordered process often completed by individuals lacking domain knowledge – lends itself to a wizard-like user interface design. The choice of a wizard-like design for the touchscreen interface does not, however, guarantee efficiency.

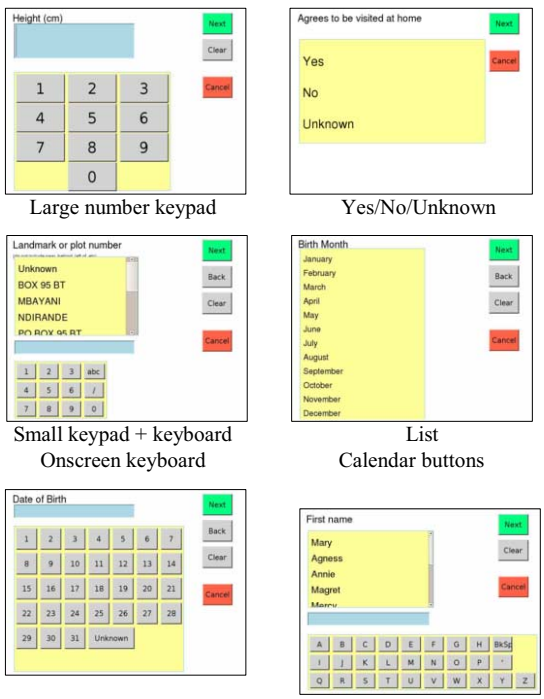

Figure 2- Six touchscreen user interface designs for collection of data at the point-of-care

HCI4D

Human Computer Interaction for Development (HCI4D) has emerged over the past decade within the field of HCI as a specialization that seeks to translate the tools and methods of HCI in developed regions for use in low-resource settings. Practitioners of HCI4D believe that the challenges and methods of HCI in developed regions will resemble the methods required in low-resource settings. A fundamental HCI principle known as "the user is not like me", which refers to the inherent differences in perspective between system developers and users, would appear to support that belief. However, the community has only recently begun to establish shared knowledge about the differences between users in low resource settings and users in the developed world [7].

Figure 1- A health worker in Malawi uses a touchscreen workstation at the point-of-care

Predictive Human Performance Modeling

Since the early 1980s, HCI researchers have addressed the problem of how to predict the efficiency with which a skilled user will be able to complete a task using a specified interface design. An HCI technique called the Keystroke Level Model (KLM) has been refined and tested to become a reliable and validated tool for predictive human performance modeling. KLM is capable of predicting the mean time for task completion by a skilled user, using a given system design, with an approximate 20% margin of error [8].

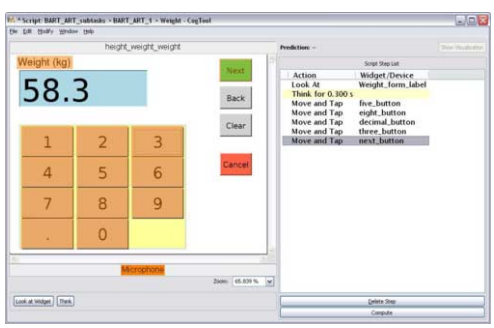

Figure 3 - CogTool interface for task demonstration using a BART user interface screenshot

CogTool is a free software application that automates the process of creating a predictive model using KLM and allows a user to rapidly create predictive models based on the user input mode, such as mouse and keyboard, voice, or touchscreen [9]. To predict a task performance time the user first draws overlays on a screenshot or mock-up of the task interface to indicate the location, size, and other properties of the widgets that must be manipulated to successfully complete a task. After preparing overlays, the user demonstrates the optimal sequence of steps required to perform a task (Figure 3).

Upon the completion of the task demonstration, CogTool generates a KLM prediction that yields a time estimate in milliseconds. The resulting estimate is the predicted total time required for a skilled user to perform a given task.

Methods

To measure relative efficiency of use, we first selected commonly performed touchscreen tasks from the EMR for evaluation. We observed novice users performing the touchscreen tasks and recorded timestamp data from their performances. Using CogTool, we predicted the skilled task performance time for each task.

Novice Human Performance Measurement

Participants

Participants were required to be adult, novice touchscreen EMR users, without prior experience using a touchscreen interface for an EMR. No prior medical training or familiarity with computers was required for the participants to be eligible for the study. Participants were health sciences students recruited at the University of Pittsburgh using posted flyers and were offered a gift card worth $25 for their participation.

Task

We selected 31 EMR tasks that are commonly performed by nurses and patient registration clerks in an ART clinic. The selected tasks did not require prior knowledge of HIV/AIDS disease management. The tasks belonged to the following clinical work processes: patient registration, patient medical history, and patient vitals collection. Patient registration tasks required patient information such as name, address, and contact details. Questions about medical history required information about the patient's prior ART treatment. Patient vitals measurement questions collected the patient's height and current weight.

User Session

We designed a five-minute training period to simulate the training provided to users of the EMR in Malawi. The session included demonstration of a representative task and a description of the core functionality of the system. Additionally we introduced concepts in the EMR that are unique to patient care in Malawi. For example we explained the concept of “ancestral traditional authority”, referring to the tribal home area of the patient, which would be unfamiliar to most participants. Once the training session was completed we gave participants an opportunity to ask any questions about the system. Following a time for questions we instructed participants to attempt to solve any subsequent problems they encountered on their own, instead of asking for help.

We prepared a series of seven mock patient encounters with an actor playing the role of a patient responding to questions from the user. The actor was prepared to play the role of all seven different patients during the user session.

Before the patient encounter began, participants practiced one representative task in the form of logging into the system with a username and password. For each patient encounter, participants performed all 31 selected tasks once. Most tasks required system users to directly ask the patient for information before entering the data into the system using the touchscreen computer. During the task performances we recorded written observations about problems that users encountered and unanticipated user behaviors.

We designed the session to last up to a maximum of one hour or seven patient encounters. Following the session, participants answered a one-page questionnaire about their computing experience and their subjective satisfaction level when using the EMR.

Event Logging

While participants used the system, the EMR software logged their activities by recording timestamp, contextual and value data entered for each user interface event. Examples of user interface events include button presses, page load time, and list item selections. For each event, the application recorded the current time, user ID, task name, and interface widget name.

Predictive Human Performance Modeling

To measure skilled efficiency of the EMR, we used CogTool to predict estimated performance times for skilled use of the 31 tasks. CogTool allowed us to rapidly build a predictive model of skilled human performance for each task.

The task models included not only the EMR user interface events, but also the time required for the user to see the question displayed by the EMR, ask the patient for information, hear the patient's response, and manipulate the interface to successfully complete the task based on the patient's answer. After we created the model for each task using CogTool, the software generated an estimated time prediction in milliseconds for each task.

Efficiency and Errors

We recorded novice performance errors to be able to analyze rates of errors in novice task performance with respect to efficiency and interface type, and to determine where novices succeeded or failed to complete tasks. Performance errors refer to any user interface event performed by the participant that was not modeled as part of the optimal sequence to successfully complete a task. For example, if a participant made a typographical error, then used the backspace button to correct the mistake, this was considered a performance error in a successfully completed task. Successful completion of a task is defined as having entered the correct value specified in the mock-patient data set for each patient encounter.

Results

The purpose of this study was to determine how efficiently novices perform touchscreen EMR tasks relative to a prediction of skilled use. To accomplish our goals, we compared

Table 1- Novice errors for six interface types

Interface type	Performed Tasks	Tasks with corrected errors		Successful tasks		Failed tasks		Tasks with missing data	
List	266	8	(3%)	250	(94%)	0	(0%)	16	(6%)
Calendar buttons	266	16	(6%)	264	(99%)	1	(0%)	1	(0%)
Yes/No/Unknown	399	13	(3%)	390	(98%)	2	(1%)	7	(2%)
Large number keypad	266	15	(6%)	259	(97%)	3	(1%)	4	(2%)
Onscreen keyboard	266	47	(19%)	252	(95%)	14	(5%)	0	(0%)
Small keypad + keyboard	133	78	(70%)	111	(83%)	22	(17%)	0	(0%)
Total:	1,596	177	(11%)	1,526	(96%)	42	(3%)	28	(2%)

novice performance times to the predicted times for skilled task performance. Additionally we analyzed the novices' rates of error and efficiency with respect to the user interface design.

We conducted a preliminary analysis of twelve out of the 31 total tasks. The user interfaces for the twelve selected tasks feature six designs (Figure 2) that are representative of the interface designs for all 31 tasks. The resulting data set contains 1,596 observed task performances (Table 1).

We created preliminary CogTool models for the use of a touchscreen EMR based on observed data collected in a pilot study.[10]

Using the results of the pilot study, we calibrated the CogTool model to improve prediction accuracy for skilled task performance. We used CogTool to predict a skilled performance time in milliseconds for each of the twelve tasks.

Participants

Nineteen health sciences students from the University of Pittsburgh responded to posted flyers and participated in the study as novices. All participants performed the 31 tasks seven times for a total of 4,123 observed task performances. All of the participants performed the seven patient encounters in less than one hour.

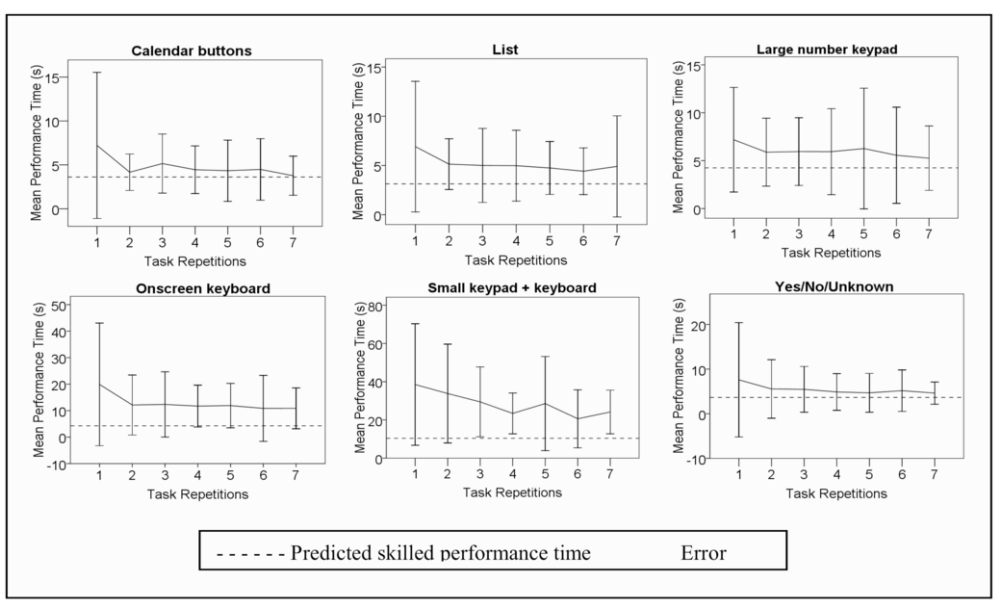

Figure 4-Mean novice task performance time by user interface design

Efficiency and Learnability

Figure 4 displays the mean novice task performance time and the predicted skilled performance time for the six interface designs. Mean novice performance for all tasks was significantly slower than the predictions of skilled use (Wilcoxon $Z = -18.58$, $p < 0.001$). Although mean novice performance times were slower, novices performed tasks faster than the predicted skilled level in 208 (13%) of the observed task performances. Novices performed within 20% of the predicted skilled level (the accepted standard margin of error for KLM predictions) in 444 (28%) of all observed task performances. Performance times for interfaces that did not require onscreen typing (Calendar buttons, List, Large number keypad, Yes/No/Unknown) were faster than performance times for interfaces that required onscreen typing (Onscreen keyboard, Small keypad + keyboard).

Errors

Table 1 displays the number of novice task performances containing one or more corrected errors and tasks successfully completed for the six interface types. Novice users completed 96% of task performances successfully. Tasks requiring the use of the onscreen typing contained the highest rate of tasks with performance errors (70%) and lowest rate of successful task completion (83%).

Conclusion

Our findings suggest that, while novice EMR users perform touchscreen tasks more slowly than predictions of skilled use, they are able to perform at a skilled level some of the time within the first hour of system use. Novices were able to perform tasks within the margin of error for the predicted skilled performance times in 28% of the task performances. This is important because a primary design goal of the EMR is to allow novice users to perform tasks efficiently and effectively.

Performance times were highly variable between novice participants for all tasks, but it is common for task performance times in user studies to vary by as much as an order of magnitude.[11] However, not all interfaces demonstrated equivalent variability in task performance. In particular the variability in performance times for interfaces containing an onscreen keyboard was noticeably higher than for other interface types. Similarly, the onscreen keyboard interfaces had the lowest rates of successful task completion and the highest rates of performance errors compared to other interface types. A possible explanation for the poorer performances with onscreen typing tasks is firstly that the keyboard used an alphabetical layout while most participants were accustomed to a qwerty keyboard layout, and secondly that onscreen typing tasks required two to seven times more touches than other tasks – increasing the overall complexity for onscreen typing tasks.

A primary limitation of this study is the differences between users recruited in Pittsburgh and the typical users of the system in Malawi. Future work will measure novice performance for users with the cultural, educational and socioeconomic background that is representative of EMR users in Malawi.

Process-Aware EHR BPM Systems: Two Prototypes and a Conceptual Framework

Charles Webster, Mark Copenhaver

EncounterPRO Healthcare Resources, Atlanta, USA

Abstract

Systematic methods to improve the effectiveness and efficiency of electronic health record-mediated processes will be key to EHRs playing an important role in the positive transformation of healthcare. Business process management (BPM) systematically optimizes process effectiveness, efficiency, and flexibility. Therefore BPM offers relevant ideas and technologies. We provide a conceptual model based on EHR productivity and negative feedback control that links EHR and BPM domains, describe two EHR BPM prototype modules, and close with the argument that typical EHRs must become more process-aware if they are to take full advantage of BPM ideas and technology. A prediction: Future extensible clinical groupware will coordinate delivery of EHR functionality to teams of users by combining modular components with executable process models whose usability (effectiveness, efficiency, and user satisfaction) will be systematically improved using business process management techniques.

Keywords:

Electronic health records, Workflow management systems, Business process management, Clinical groupware, Modular architecture

Introduction

Productivity is the ratio of an output to the input required to generate it. EHR productivity is EHR output—value of accumulated digitized patient data—divided by EHR input, or cost to obtain this data. The relationship between EHR effectiveness and efficiency is mediated by EHR processes, and EHR productivity cannot be improved without flexible EHR processes. The maximum EHR productivity that can be achieved within an interval of time is a function of all three of initial EHR effectiveness, efficiency, and flexibility. The concept of EHR productivity is relevant to both meaningful use of EHRs and EHR business process management.

A concise and common sense description for meaningful use of an EHR is "Processes and workflow that facilitate improved quality and increased efficiency" [1]. This resembles BPM's systematic optimization of process *effectiveness*, *efficiency*, and *flexibility*. At this point it is worthwhile to define some terms:

- Systematically optimize: improve in a consistently organized manner
- Objectives to be optimized
  - Effectiveness: ability to achieve output goals
  - Efficiency: ratio of output goals to required input resources
  - Flexibility: adaptability to changing goals and environmental conditions
- Environmental conditions
  - Dynamic: changes over time
  - Uncertain: difficult to predict
  - Risky: rewards and penalties apply

A closed-loop control system uses the difference between observed and desired output to automatically generate system inputs that will reduce the observed difference (Figure 1). For example, a thermostat compares observed temperature to desired temperature to decide whether to turn a heater on or off. Feedback control theory [2, 3] includes models and techniques to automatically optimize system behavior in response to changing environmental conditions. A negative feedback control system formulation of BPM, applied to systematic optimization of EHR performance, serves a useful purpose. It places EHR BPM into broader historical context that leads back to cybernetics and control theory [2].

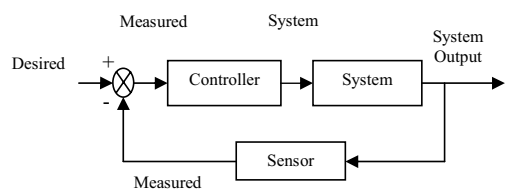

Figure 1 – Negative Feedback Control

Process-aware [4] EHR business process management systems are ideal vehicles for implementing closed-loop patient care systems [3] because there is a means—workflow engines executing process definitions—to directly influence EHR behavior and state. For example, minimizing the difference between observed and desired measures of health population status, or between observed and desired levels of medical practice efficiency, are forms of closed-loop optimization.

Future evolution of EHR technology will create greater effectiveness, efficiency, and flexibility in the face of dynamic, uncertain, and risky environments. The only practical means by which this will be achieved will be if EHRs include within their very technological nature the ability to systematically change internal processes and workflows to better meet set objectives while operating in typical environments. For these reasons the next generation of EHR systems will be process-aware EHR business process management systems.

Materials and Methods

Two EHR BPM Prototypes

We developed EHR BPM prototype modules to systematically optimize EHR effectiveness and efficiency. These prototype modules were built on a free and open-source EHR workflow management system (WfMS) with a modular component-based architecture. (Specialty-specific user interface and non-user interface components are combined into specialty-specific modules controlled by a workflow engine executing specialty-specific process definitions to generate workflow-based clinical groupware used by 4000 users at 300 sites in fourteen specialties [5, 6]).

Systematic Optimization of EHR Efficacy

For our measure of EHR effectiveness we chose a combination of compliance with medical protocols and control of key clinical values that affect patient health. PROCARE stands for PROvision-based Clinically Active Reporting Environment (Figure 2). PROCARE is a closed-loop patient care system that uses a patient class event hierarchy to trigger process definition execution by an EHR workflow management system. The patient class event system and associated process definitions improve measures of clinical performance over time.

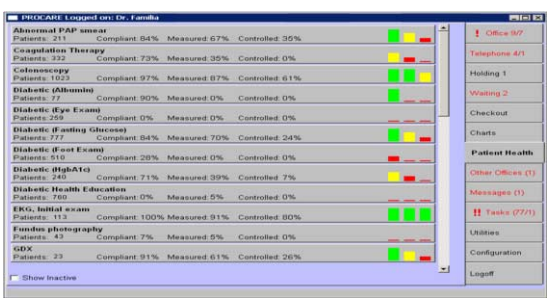

Figure 2 – PROCARE Clinical Dashboard

A provision is a forward-looking restriction or qualification in a contract or agreement. For example, a patient can be in a predefined class of patients provided they meet that class's predefined criteria (age between 0 and 18, BMI > 30, etc.). A patient class event hierarchy (Figure 3) detects at risk patients, calculates aggregate statistics that summarize clinical performance for a patient population, and automatically triggers workflows to help manage risk.

PROCARE's clinical summary dashboard (Figure 2) displays for each measure of clinical performance four numbers (corresponding to the four levels of the patient class event hierarchy): number of patients in the class for which the measure applies, percentage of patients in each class that are compliant with a predefined protocol, percentage of patients for whom appropriate and timely measurements are available, and percentage of patients for whom observed measures are controlled (within target normal limits).

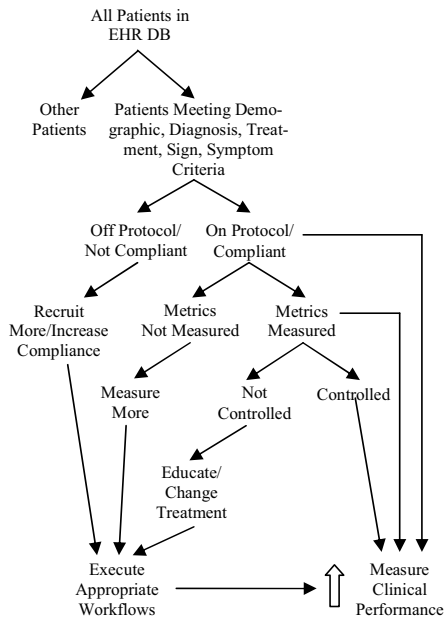

Figure 3 – Patient Class Event Hierarchy

Selecting a measure of clinical performance (such as colonoscopy in Figure 2) displays a patient list management screen (not shown) for creation or refinement of the policies that link patient class events to automated workflows. For example, process definition steps could include role or user work items, work items that appear when the patient is physically present, instructions that appear automatically whenever a patient chart is opened, or messages to external systems that trigger email or phone calls. Execution of appropriate workflow moves patients from non-compliance to compliance, unmeasured to measured, and uncontrolled to controlled categories, causing a shift from red to yellow to green graphical indicators on the summary dashboard.

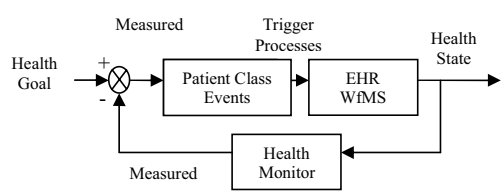

Figure 4 – PROCARE: Closed-loop Population Management

PROCARE uses a BPM approach (automated triggering of process definitions to systematically improve a measure of EHR effectiveness) to implement a closed-loop patient care system (Figure 4).

Systematic Optimization of EHR Efficiency

For our measure of EHR efficiency we chose to improve medical practice throughput and throughput time. PROCESS stands for PROcess Comparison for Efficient System Specification. PROCESS uses process mining [7] techniques to visualize, compare, and improve ambulatory EHR patient encounter task workflows. PROCESS is directing at improving processes in medical practices by:

1. Generating process models of existing practices.
2. Comparing measures of productivity (throughput and throughput time).
3. Explaining differences in productivity in terms of differences in processes.
4. Suggesting process improvements for low productivity practices.

We randomly chose nine pediatric practices relying on the same EHR workflow management system. We used process mining and visualization tools to compare throughput and throughput times across the practices for October (traditionally a busy month for pediatricians).

We looked for process activity patterns that might explain differences in global productivity measures (Figure 5). For example, practices 5 and 7 had high volumes but low throughput times, and displayed an accumulation of tasks between tasks H (Get Patient) and E (Current Meds) in Figure 6, which are both tasks for the nurse role.

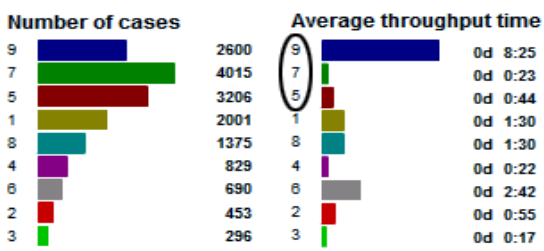

Figure 5 – Nine Medical Practices, Productivity Statistics

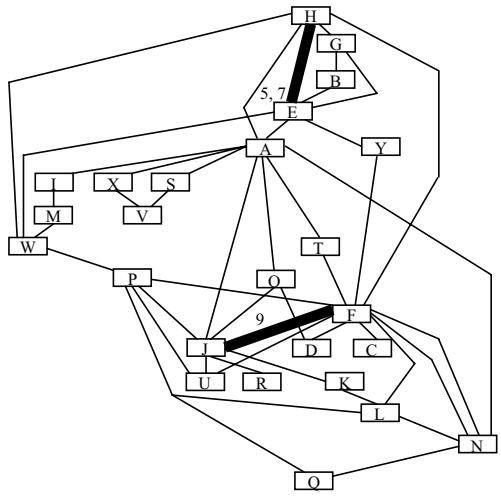

Figure 6 – Nine Medical Practices, Process Model

In contrast practice 9 had lower volume but a dramatically higher average throughput time (Figure 5), and an accumulation of tasks between tasks F (Examination) and J (New Note), which rely on the physician role, a scarcer (and more costly) resource. This triggered investigation and consultations between the practice and a practice skills instructor to change and improve workflows.

In contrast to PROCARE, where our object is to systematically improve EHR WfMS effectiveness, our object with PROCESS is to systematically improve EHR WfMS efficiency, resulting in Figure 7 as a conceptual mapping back to the negative feedback control model initially presented.

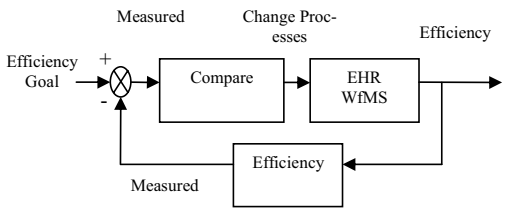

Figure 7 – PROCESS: Closed-loop Process Improvement

Practical and Conceptual Results

Our foray into EHR BPM had practical and conceptual results.

At the practical level, the PROCARE prototype played an important role in communication with regional clinical stakeholders using the same EHR WfMS. We used the prototype to explain the patient class event hierarchy and plan an enterprise-wide version of PROCARE as part of a regional health information exchange. The PROCESS prototype has been a valuable artifact to focus our internal discussion regarding developing a new service to provide to our EHR WfMS customers. Initial inspection of the resulting process models has already triggered useful practical investigations directed at improving medical practice workflows.

At a conceptual level, we became convinced that a business process management approach to systematically optimizing EHR effectiveness, efficiency, and flexibility is the most consistent, comprehensive, and useful framework within which to achieve meaningful use of EHRs at the point of care. EHR workflow engines, executing process definitions, can coordinate specialty-specific components, modules, and workflows to provide approximate specialty-specific clinical groupware solutions. These EHRs will still require BPM process optimization techniques to realize their full potential.

Combining EHR with BPM technology promises to (1) model and simulate interactions among physicians and other clinical and non-clinical staff, systems, and EHR components to create a shared mental model of how to optimize care coordination processes and results; (2) coordinate and manage handoff of patient care tasks within and across organizational boundaries; (3) provide real-time feedback to physicians and other care coordinators about care-in-progress to support in-line patient care process adjustments; and (4) monitor care coordination outcomes compared to performance targets and systematically improve care coordination process flows.

Conclusion

As summarized in Aalst and van Hee [8], the development of information systems has passed through four phases: (1) decomposition of applications, (2) movement of data into shared databases, (3) movement of user interface management out of applications, and (4) movement of process management out of applications into workflow management systems. Compared to other industries, today's EHRs, while complex and sophisticated in many ways, have not yet migrated process management into foundational workflow management systems.

Non-process aware EHRs *do not distinguish between unitary tasks at the same fine degree of granularity* as EHR WfMSs. Traditional EHRs often have high resolution screens with a multitude of simultaneous data review and entry and order entry options. Multiple user events, spanning multiple tasks, are often committed together to the underlying database, conflating together logically separate workflow steps. In contrast, an EHR WfMS typically presents just the data review and entry and order entry options on each screen that are relevant to single step in a task workflow sequence. For example, a nurse checking allergies and then current medications are two different tasks that at highly granular resolution should be distinct and acquire different time stamps.

Non-process aware EHRs *do not capture all the potential meaningful timestamps for those events that they do log*. They may log when data and orders are committed to a database but they do not typically log when tasks are first available to be accomplished, when they begin, when they complete, and other relevant timed-stamped events such as cancellation, postponement, or forwarding. Much of this missing temporal information is invaluable for understanding why bottlenecks occur, why certain tasks are subject to rework, and what slack resources are available elsewhere in the system.

Non-process aware EHRs, even if their event logs result in useful process models and actionable insights, *lack means to actively influence changes to workflow*. There are no process definitions or workflow engines to execute them; so there are no process definitions to change and thereby influence and improve effectiveness and efficiency. With respect to EHR effectiveness, a patient classification system without ability to trigger automated workflow is a passive reporting system (in which reports must be handed to staff for disposition, "Please put a note in each patient's chart so that the next time they have an appointment…"). A more active reporting system feeds directly back to a workflow management system to automatically perform useful tasks. With respect to EHR efficiency, even if a process model has an obvious flaw, there is no way to consistently and automatically deflect behavior at critical process junctures in order to improve throughput and throughput time.

In summary, compared to process-aware EHR workflow management systems, traditional EHRs (1) do not track tasks at high degree of resolution, (2) do not distinguish among a large number of useful time stamped events, and (3) have no means for process model insights to drive improvements through use of automated workflow. The next necessary step in the evolution of ambulatory EHRs is squarely at the intersection between electronic health record systems and workflow management/business process management systems. These hybrid clinical groupware systems will be more systematically optimizable than traditional EHRs with respect to clinical effectiveness, practice efficiency, and user satisfaction (that is, usability).

There are a number of research topics that we realize are relevant to EHR effectiveness and efficiency improvement mod-

ules such as herein described, including the relationship between process definitions and clinical guidelines [9, 10, 11]; ambulatory process patterns [12], mining [13], and flexibility [14]; and especially learning business process models [15]. As we continue development of EHR BPM modules, we will continue to absorb insights from these and other business process management and medical informatics research areas. In turn, we hope that our and other process-aware EHR systems can become useful sources for process data and case studies, and test beds for further research ideas and initiatives.

Acknowledgements

Many thanks to Prof. Wil van der Aalst for taking time to answer our questions about business process management research.

We also wish to acknowledge the larger academic medical informatics and business process management community. Work-a-day experience (and pressure) of maintaining and enhancing an existing EHR WfMS/clinical groupware product serving millions of patients, thousands of users, and hundreds of ambulatory medical offices does not typically afford us the opportunity to consider the larger intellectual enterprise in which we play a small part. Without the Web and the generous and open manner in which medical informatics and business process management research ideas and results are shared, we would lack access to information resources to contextualize what we have done and hope to do.

Understanding Resistance towards Electronic Patient Health Data in South Australian Family Practice

John Knight, Margaret Patrickson, Bruce Gurd

International Graduate School of Business, University of South Australia, Adelaide, Australia

Abstract

This paper reports the results from a survey of 131medical practitioners in South Australian General Practice concerning adoption of a computerised system for storing and potentially amalgamating health information from several practices. Practitioners were primarily influenced by the positively perceived potential for such technology use to improve patient health and well-being outcomes and secondarily by the negatively perceived potential for unwanted change in the status, control and autonomy of their professional role. Practitioner attitude reflected how they resolved the competing influences. The data suggest that strategies for implementing such systems should address individual perceptions by increasing belief in the potential for patient improvement or by decreasing belief of the inevitability of unwanted role change.

Keywords:

Medical informatics, Family practice.

Introduction

This paper explores potential adoption of amalgamating Health Informatics (HI) technology by South Australian practitioners in general practice medicine (GPs). General Practice in South Australia mostly operates as solo practices, partnerships or incorporated bodies averaging 2.5 GPs each and, estimated to see 85 percent of healthcare consumers annually, is integral to delivering any comprehensive, coordinated and continuing healthcare strategy to the wider health system [1-3]. Within this scenario, HI is promoted by all levels of government as an emergent interdisciplinary label for the application of computers to improving the efficiency and effectiveness of healthcare management [4]. Yet implementing HI systems requires adoption of electronic patient records and potentially the need to reengineer traditional workflows and disrupt existing business and clinical processes [5].

Previous to this study, Australian Governments had targeted GPs with funding initiatives to increase the use of computers in general practice medicine [1]. Nowadays almost all practices have at least one computer, and some are seen to have designed their processes to increase the use of technologically supported systems in order to increase practice income [6]. Nonetheless a study between 2003 and 2005 reported that some Australian GPs who had access to computers and clinical software chose not to use them, and only a third kept all patient data in an electronic format [6]. Other findings indicate HI systems that are viewed as improving diagnostics, reproducing accepted models of clinical reasoning or providing immediate patient benefit have been adopted, while those aimed at improving the overall efficiency and effectiveness of healthcare appear to be have been resisted [7-9].

Understanding why people accept a particular innovation remains a challenging and complex issue, and medical practitioners have been cited as classic examples of 'professional' populations where understanding decisions of what innovations are adopted and when has been especially problematic [10, 11].

Method

The purpose of this study was to test tentative hypotheses from an earlier qualitative enquiry. Directed at a small sample of GPs to try and capture potential reasons why they tend to resist (or not) adoption and implementation of HI systems, findings suggested sources of GP resistance stemmed from deeply held GP beliefs, feelings, anxieties and values that could be challenged by such technology adoption [4]. The importance attached to forces pushing for resistance reflected GP beliefs about their professional and organisational role and the use of technology in their workflow. Findings also suggested motivation for adoption reflected GP belief in the efficacy of the technology to improve health outcomes of their patients and the wider population. The importance attached to forces pushing for adoption reflected the perceived relevance to the GPs' role of such potential for improvement. Strategies aimed at increasing such technology uptake by providing financial incentives enhanced any motivation to adopt, particularly within the practice boundary. However, perception of change needed in environmental antecedents which impacted the GP's relationship with their patient was seen as undesirably changing the GP role in the delivery of healthcare.

These data led the authors to formulate a series of hypotheses about the relationships between these forces influencing GP intention, rewritten as five main hypotheses (Table 1). Testing these hypotheses formed the basis for a questionnaire distributed to a representative sample of GPs, and the findings are

presented in this paper. Drawing from literature and based on the recurrent themes, propositions and hypotheses derived from the qualitative study, a 'concern' dictionary was developed to test the hypotheses and explore potential strategies to reduce resistance. The resultant conceptual model (Figure 1) frames the hypotheses and reflects the view that GP resistance towards new HI technology adoption is the outcome of the perceived advantages (or otherwise) of potential changes in valued antecedents associated with their role.

Table 1- Hypotheses concerning GP resistance towards new HI technology adoption

H_1: *There is a direct positive relationship between the potential for new HI technology to undesirably change their role (C1) and emergent GP resistance to adopting new HI Technology (DV)*

H2: *There is an indirect negative relationship between the potential for HI technology to improve patient outcomes (C2) and emergent GP resistance to adopting new HI Technology (DV).* ***H2a:*** *There is a direct negative relationship between GP perceptions of the potential for HI technology to improve patient health and well-being outcomes (C2) and the potential for undesirable change to the GP role (C1).*

H3: *There is an indirect positive relationship between the context in which they perform their role (C3) and emergent GP resistance towards adopting new HI Technology (DV).* ***H3a:*** *There is a direct positive relationship between GP perceptions of the context in which they perform their role (C3) and the potential for undesirable change to the GP role (C1).*

H4: *There is an indirect negative relationship between the influence of incentives on HI technology adoption decision-making (C4) and emergent GP resistance to adopting new HI Technology (DV).* ***H4a*** *There is a direct negative relationship between GP perceptions of the influence of incentives on HI technology adoption decision-making (C4) and the potential for undesirable change to the GP role (C1).*

H5: *There is an indirect positive relationship between the attributes of a GP role (C5) and emergent GP resistance to adopting new HI Technology (DV).* ***H5a:*** *There is a direct negative relationship between GP perceptions of the attributes of a GP role (C5) and the efficacy of new HI technology (C2).* ***H5b:*** *There is a direct negative relationship between GP perceptions of the attributes of a GP role (C5) and the role context (C3).* ***H5c:*** *There is a direct negative relationship between GP perceptions of the attributes of a GP role (C5) and the influence of incentives to adopt new HI technology (C4).* ***H5d:*** *There is an indirect positive relationship between GP perceptions of the attributes of a GP role (C5) and the potential for undesirable change to the GP role (C1).*

Anticipated to underpin GP resistance, measurement of change to the GP role focused on the perceived potential for change to their autonomy, control, status and relationship with their patient. Measuring context antecedents focused on collecting information on the extent to which perception of the environment (such practice characteristics as the number of practice GPs and nurses and the current use of clinical and billing software) influenced GP resistance. Anticipated as a positive force for adoption, measurement of the potential for HI technology use to underpin improved patient health and well-being outcomes focused on the relevance of improvement in different patient populations. The survey also sought to measure the influence of incentives and what modifications in existing strategies might potentially improve the penetration of HI technology use in GP practice. This included the extent to which incentives were seen to address the value of the GP role, data, participation in policy decision-making and patient attitude toward GP use of such technology. The survey also encompassed individual and role attributes that in combination potentially ameliorated or exacerbated GP perceptions of other influences (such as their self-perceived professional, technological and innovative traits). Interview content had indicated experience as a GP and hours worked per week on direct patient care were potentially influential, while literature on professionals and technology adoption studies suggested alignment with professional organisations, age and gender may be relevant to GP attitude [12, 13].

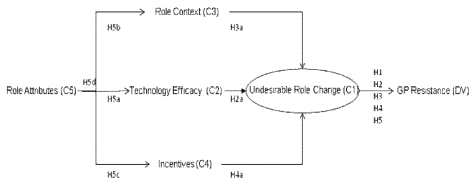

Figure 1- Theoretical Model of Forces of Influence on GP Resistance

Pre-testing the instrument resulted in rewording of ambiguous questions, alternate shading to better differentiate questions and an indication of the estimated GP time commitment being added to the survey introduction. Respondents were targeted from member practices of three South Australian Divisions of General Practice. This gave a potential sample size of 650 GPs from 210 practices. Questionnaires were distributed resulting in a return rate of 131 usable replies (20.15%). The sample demographic profile was found to roughly reflect both the South Australian and Australian GP population.

Data Analysis and Results

Data analyses were performed using the statistical computer program SPSS (version 16) for Windows. Factor Analysis was performed to reduce each construct of items to fewer factors, to make the data set more manageable and to facilitate testing a theoretical model with valid variables [14]. Principal Axis Factoring was chosen because the aim was to describe structure and using Squared Multiple Correlations provides more accurate estimates of initial communalities [15]. Only factors with eigenvalues >1 were extracted and only items correlating at >0.4 with the factor were considered. The single factors extracted were transformed into new variables.

The endogenous construct readily transformed to one factor. To avoid confusion for the sample, the item scale used reflected a high score for intention to adopt new HI technology. By reverse scoring all other items, a high score in the subsequent factor indicated an intention to *not* adopt. Examination of the case-wise diagnostic statistics identified 28 cases (21.9%) showed more intention to resist than take-up new HI technology. The constructs of influence seen to underpin GP motivation to adopt new HI technology also readily transformed to single factors. A high score in the subsequent Technology Efficacy Factor indicated a strong belief in the potential of HI technology to improve patient outcomes. A high score in the Incentives Factor indicated a strong belief in the positive influence of financial incentives on GP adoption.

Factor correlation showed all five factors to have the anticipated significant relationship with GP intention to resist. The results also suggested the relationship between role attributes with GP resistance may be fully mediated by the perceived potential for undesirable role change as hypothesised. However, the influence of GP belief in the technology efficacy and the influence of financial incentives were at best partially mediated by the perceived potential for undesirable role change, while the influence of GP's context was not mediated at all. Also, the anticipated influences of both GPs' context and role attributes were reversed. It is noteworthy that the correlation between GP intention to resist and technology efficacy and undesirable role change were of similar strength, casting doubt on the anticipated mediating effect of undesirable role change on all other influences. Thus factor correlations supported the hypothesised significance (albeit not always the pathway) of relationships between the original constructs of influence and GP intention to resist in H_1, H_2, H_3, H_4 and H_5. However the anticipated mediation of the GPs' role attributes relationship with GP intention to resist by the GP context (H_{5b}) and financial incentives (H_{5c}) was not supported, nor was the anticipated mediation of the GP context influence on GP resistance by the potential for undesirable role change (H_{3a}) supported. Yet a significant relationship between financial incentives and belief in technology efficacy had not been hypothesised.

A series of ANOVAs were carried out to examine the effect of the categorical variables on the derived factors. The *F*-values showed solo GP status, accreditation, practice nurses employed, experience as a GP and AMA membership all had significant relationships with GP intention to resist adoption. On the other hand, none of the categorical variables had a significant relationship with GP context and incentives, while hours worked, gender and practice designation had no significant relationship with any of the factors or with GP intention.

Analysis to determine whether the derived factors were predictive of GP intention to resist utilised Exploratory Factor Analysis through multiple regression. The first model with all categorical measures of attributes showed their coexistence had the effect of suppressing the previously identified significance of some of the relationships with GP intention. While not disproving the significance of the relationships per se, this highlighted they were only significant outside of the regression model. Nonetheless, this appeared to illustrate the individual and practice attributes did not have significant individual or collective direct relationships with GP intention and were more likely, singularly or together, to indicate a moderating influence(s) on the relationships of the derived factors with GP intention. The addition of Role Context as a predictor predicted the DV significantly better, and addition of Incentives as a predictor explained 33.3% of the variance in GP intention. This model also suggested the relationship between Role Context and GP intention may in some manner be mediated by the influence of Incentives, which was tested through mediated regression [16]. Yet this relationship was not clearly supported by this sample. Even so, it seems conceptually reasonable that the influence of GP consultation type range and frequency on GP intention to resist adoption was, for some GPs at least, impacted by incentive strategies that attempted to increase GP adoption of new HI technology. It is noteworthy that the complete loss of significance of the range and frequency of their consultation types in this model, meant there was no evidence of direct influence on GP intention in the presence of the other factors. While the addition of Role Attributes as a predictor predicted GP intention significantly better, the anticipated significance of the direct and indirect Role Context relationships with GP resistance were not supported by this sample. Thus Hypotheses H_3, H_{3a} and H_{5b} were not supported wholly or in part. The addition of Technology Efficacy as a predictor suggested belief in the efficacy of the technology may in some manner mediate the influence of both incentives and role attributes on GP adoption intention. Mediated regression suggested the influence of Incentives was only partially mediated by Technology Efficacy. While this relationship had not been hypothesised it seems conceptually reasonable that for at least some GPs, belief (or not) in the potential of new HI technology to improve patient outcomes would mediate the impact of financial incentives on GP intention. Mediated regression also showed the influence of Role Attributes on GP intention was partially mediated by Technology Efficacy. Hypothesis 5a was therefore supported for this sample.

The addition of the perceived potential for undesirable role change as a predictor to the model represented all the constructs and the categorical variables and explained 65.2% of the variance in GP intention to resist adoption ($F_{(21, 97)} = 8.658$, $p<.001$). This also suggested the influence of Role Attributes on GP intention was in some way mediated by Undesirable Role Change, while testing showed Role Attributes was partially mediated by Undesirable Role Change, showing Hypothesis H5d was supported. However there was no change in the significance of Technology Efficacy relationship with GP intention, so Hypothesis H2a was not supported. Similarly, there was no change in the significance of Incentives relationship with GP intention, so Hypothesis H4a was not supported. A summary of how the study hypotheses were either supported or not by these regression results can be seen in Table 2.

Table 2- Summary of support for Hypotheses

H_1	F_1, DV	Yes
H_5	F_5, DV	Yes
H_2	F_2, DV	Partially
H_3	F_3, DV	Partially
H_4	F_4, DV	Partially
H_{5a}	F_5, F2	Partially
H_{5d}	F_5, F_1	Partially
H_{2a}	F_2, F_1	**No**
H_{3a}	F_3, F_1	**No**
H_{4a}	F_4, F_1	**No**
H_{5b}	F_5, F_3	**No**
H_{5c}	F_5, F_4	**No**

In order to establish whether a more parsimonious representation of relevant predictive factors of influence on GP resistance could be identified, hierarchical linear regression was performed with only factors that had a significant individual relationship with GP intention in the presence of the other factors. This excluded the Role Context Factor and the categorical individual and practice attributes as predictive variables. The subsequent model ($F_{(4, 122)} = 44.772$, $p<.001$) explained 59.5% of the variance in GP intention. Although not predicting GP intention as accurately as the model with all the constructs and categorical variables, this model was seen to represent the key common factors influencing GP attitude formation and identified the potential for HI technology to improve patient outcomes as statistically the most important factor in predicting GP intention to resist adoption. Although not statistically significant, the negative β-weight of the Technology Efficacy and the positive weight of Undesirable Role Change was seen to increase, giving the net effect of widening their relative impact on GP intention to resist. This could arguably be the outcome of change in the influence of Incentives on GP resistance in the presence of the categorical variables. This suggested the range and frequency of consultation types in combination with individual and practice attributes may be more appropriately seen as indicators of a moderating influence on the relationship between Incentives and GP resistance. Thus, moderation of the Incentives Factor and GP resistance relationship may be indicated by different combinations of individual and practice attributes for different GPs. Also, the anticipated indirect relationship between the Role Attributes and Undesirable Role Change Factors emerged as a significant direct relationship. While not hypothesised, the study showed a direct relationship between Role Attributes and GP resistance was probable.

Discussion

It seems conceptually reasonable that the potential perceived for undesirable changes to the GP role would be a barrier to GP adoption, while resistance would be abrogated by belief in the potential of the technology to improve patient health outcomes. Also, that GP use of HI technology and the propensity to use technology would be influence the perceived desirability of any potential for technologically facilitated change to their role. It finally seems reasonable that the influence of incentives targeted at increasing GP uptake of new HI technology on attitude formation would be moderated by the range and frequency of consult types in combination with other individual and practice attributes. This thinking is represented in the modified research model (see Figure 2).

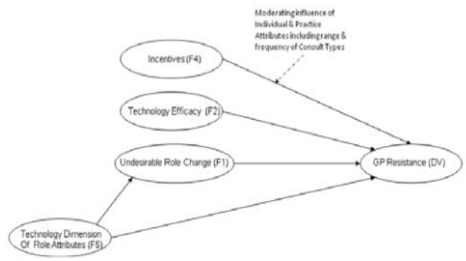

Figure 2- Most parsimonious hypothesised Model.

The role attribute construct supported the focus of [13] and others, regarding the importance of the current use of technology in understanding new technology adoption, yet it was GP use of and propensity to use such technology compared to other GPs that became significant. Similarly, the Role Context Construct became exclusively a measure of the GP consultation types as a consistent indicator of resistance, with Factor Analysis excluding perceptions of the healthcare system, profession and practice context antecedents. Although this may be seen to reflect inappropriately formulated questionnaire items, it also confirmed consistent themes uncovered in this research:

- Unlike extant literature concerning adoption of new technology with non-professionals [13], GPs did not generally see mastering the use of computers for data entry in the practice of medicine as a barrier to adoption, particularly if use was evidence-based.
- The autonomous nature of the GP role in an environment of demand for their services essentially means any change in their workflow must be voluntary.
- The GP did not spend time considering the potential for change unless they believed they could exert some immediate control over change outcomes.
- The smaller the practice, the more likely practice attributes could be seen as an indicator of GP attributes. Hence the more important it is to address individual GP concerns over practice uptake of change.

Conclusion

The poor uptake of HI technology by GPs may simply reflect the ineffectiveness of past and existing strategies and challenges contemporary thinking in aiming to design generalised models of technology adoption behaviour. Considering an individual's interaction with the system and context makes this change behaviour more comprehensible and supports the thinking of [17, 18] when they cite the importance of understanding individual, system and context interactions.

These findings indicate anticipated change to role or valued contextual antecedents were potentially powerful inputs to emergent resistance. Thus adoption strategies should consider the collective influence on GP perceptions of individual and practice attributes (such as the range and frequency of consultation types, current GP use of HI technology and current practice implementation and use of HI technology). Such focus

would better emphasise the relevance of patient populations potentially benefiting from such technology adoption and be more likely to overcome belief of the inevitability of undesirable change to the GP role. Effective strategies to overcome resistance to HI technology diffusion should thus emphasise benefits to the GPs' patient rather than change to their role.

Financial incentives would more likely be effective in changing GP practice behaviour for example, if uptake was within the realm of GP control and they addressed such specific concerns as the potential for incurring unremunerated practice costs. A situation could then be created where the forces for adoption were stronger than the forces for resistance. However this research suggested certainty about unwanted outcomes could raise the impact of factors that encourage rejection and stategies would be less effective if non-adoption, resistance or rejection was predicated on GP perception that implementation would lead to fundamental change to their role. Then, a strong motivation to move away from adoption would likely underpin an imbalance of forces favouring resistance. Adoption can then be seen as the outcome of the relative strengths of opposing forces, not simply a consequence of diffusion.

This research was directed towards understanding the reasons for GP resistance as the identified gap in the existing body of knowledge [19]. It is anticipated this research provides theoretical grounding and empirical evidence for the direction of future investigations into acceptance of technological innovation in different contexts and settings, particularly by the medical professional in a healthcare context. The exploratory nature of this research uncovered GP and practice attributes of potential influence, yet their significance to GP resistance was neither proved nor disproved. This allows for future research to theorise different combinations of individual and practice attributes as potentially indicative of moderating influences on the process of GP attitude formation.

Abstract

The medical record is a key component in the modern health systems, a fundamental basis of higher functionalities that guaranties quality care and the possibility of improved clinical management. The dissemination of information systems for the electronic medical record (EMR) has a growing acceptance and use in developed countries. This type of recognition however has not been widespread in Latin America. Realizing this we conducted a web survey to users of a Latin American medical portal to assess their perception of the EMRs usefulness. Among the results we found that over 90% of respondents were in favor of its use, with values that exceed 80% in the analysis of the utilities by categories. More in-depth studies are needed to determine the reasons for the lack of dissemination and implementation of EMR in our region.

Keywords:

Data Collection, Computerized Medical Record Systems, Medical Records.

Introduction

There is now enough evidence that supports the fact that electronic health records improve quality of care and that it optimizes the costs of the process [1]. Despite the evidence, the use of this tool has not flourished in Latin America.

The Institute of Medicine (IOM) stated that the electronic clinical record should be a longitudinal collection of electronic health information provided by any member of the healthcare team. They also stated that records should provide real time access to authorized users; the EMR should also provide knowledge bases and decision support systems to improve the quality, safety and efficiency of patient care [2]. Some observational studies found that there are practical, logistical and organizational constraints that reduce the effectiveness of the traditional paper record to store and organize the growing number of clinical observations. The electronic medical record (EMR) was designed to overcome many of these limitations, as well as to provide additional benefits that can not be obtained through a static view of events [3-5]. These technologies have spread rapidly in the developed world, with varying degrees of acceptance by professionals. Many studies have evaluated its utility either from the use or the selection of the system [6-8] but in much of Latin America the use of an EMR has not expanded the same rate as the rest of the world [9]. This may be due to either economics or adoption resistance from healthcare personnel [10-13]. Several studies on EMR usefulness have been published in the United States and Europe [14-16], with favorable results in the values of utility and degree of agreement with these informatics systems.

The objective of this paper is to evaluate the perception of usefulness and use of EMR to users of a Latin-American medical web portal.

Materials and methods

This work was done in the medical web portal called IntraMed (www.intramed.net) that is a medical network of science content with distribution in the geographic area of Latin America, with over 250,000 subscribers and a frequency of use of approximately 50,000 different users per month. The site has the functionality that enables the professional specialist or user to target relevant content. The site has 480 main pages with knowledge subsets for 32 medical specialties by region (15 countries). In each of these dynamic pages by specialty, the content is structured with news, medical articles, continuing medical education and events. There is also content common to all non-medical specialties and notes of general interest.

The study was conducted using an "e-research" framework, a study/survey methodology that uses the Internet to obtain the results [17]. The survey was developed using a structured questionnaire available online to users registered to the site. It was available at the site between July 15 to August 15, 2008. This inquiry assumed that the "online" study population was limited to Internet users accessing this website. The study was cross-sectional and descriptive. The characteristics of the electronic survey were to be in structured format and optional filler.

Measuring instrument: The survey was developed based on a Likert scale of 5 points, covering the classification from very

useful to useless. The development of the survey was supervised by the epidemiology and statistics area of the Hospital Italiano de Buenos Aires. Survey validation was done with 20 users who analyzed and answered 50 questions. After analysis the total number was reduced to 40 to eliminate the confusing or non relevant.

The survey was available for all users once they entered the Intramed web portal, after validation by username and password. At the survey introduction, the prospective survey taker had the option to answer at this moment, do it later or not answer. After this they would either continue with the survey or be thanked. In either situation the survey would not be re-requested when accessing the site at subsequent times.

If the user agreed to take the survey he or she was presented with text explaining the purpose of the study and the voluntary acceptance of their data as part of that investigation. The responses were stored in a database that conserved the demographic information and the selected choices with absolute technical impossibility of identifying the user's personal data.

The survey assessed the perception of users regarding the functional benefits of the EMR in the following domains (Figure 1):

1. **Functions of the proper EMR**: registry of the progress notes, list of medical problems.
2. **Documentation functions**: recording lab results, registration of images, scanning and storage of physical documents in the EMR, documentation of vital signs.
3. **Functions related to preventive care and decision support system**: record of immunization, registered allergies warning, and reminders about the implementation of preventive practices.
4. **Prescribing and ordering functions**: medication registration, consult medication prescriptions recorded and print them.
5. **Referrals related functions**: to receive response of the Referrals professionals.
6. **Health education and access for the patients (PHR)**: submit reminders to patients by phone or mail, to enable patients to access information about their histories prior authorization of the professional, create and print education programs and information for their patients.
7. **Administrative functions**: would be able to use administrative data from other centers that use the system, data coverage from patients.
8. **Interoperability**: the ability to encode diagnosis of their patients, share their recorded information of the patients with other professionals.

We also requested the following: (Figure 2):

- Year of professional certification (graduation)
- Work location(s).
- Private or public or both workplaces.
- If they used some type of personal device (PDA) and/or computer systems for recording patient information (in cases that this answer was yes, the survey instrument registered the type of system they used).
- Describe main shortcoming of the system.
- Training received (or did not) to use the system.
- The availability of technical assistance.
- The registry format used.
- Finally, if they would continue using traditional registration in paper and if they would use an EMR.

The results were expressed with frequency and percentage.

Results

The survey was available at the medical web portal for users of this website, between July 15 to August 15, 2008. During this period over 16,702 different users entered in the portal (exposed population) of whom 5171 users responded to the survey (30.96% response rate), 70% were Argentineans. Sixty-five percent (65%) of the respondents worked in pediatrics, internal medicine, surgery and gynecology.

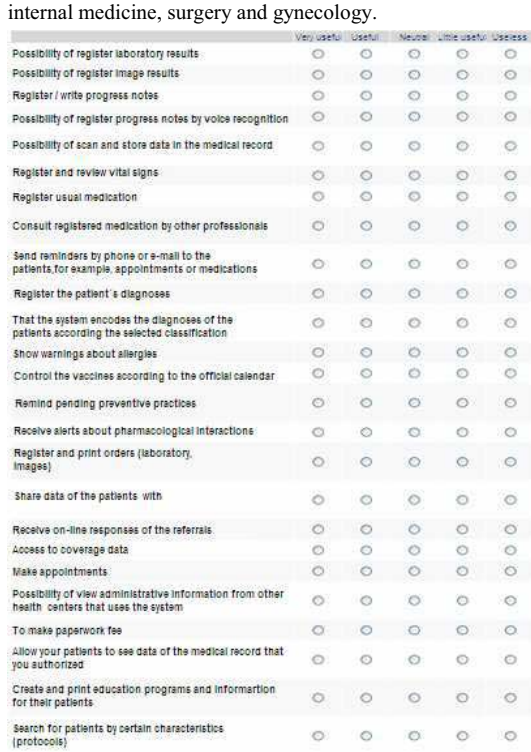

Figure 1 – Questions as useful domains.

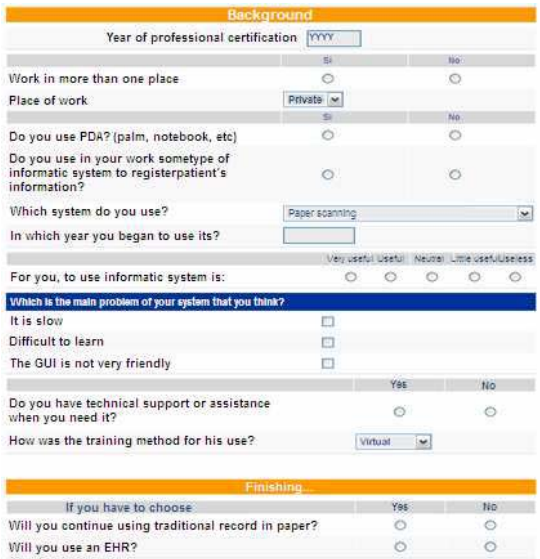

Figure 2 – Context questions.

Context Characteristics

With regard to the context of the workplace of the respondents: 69% of professionals worked in more than one place, with 47% of those working in both the private and public sectors. Sixty-one percent (61%) used personal electronic devices, and 56% had an informatic system at their workplace (12% digitizing, 31% own informatics developments, the rest divided between document scanning systems, vendors development and other systems). Thirty percent (30%) began using devices less than 5 years ago, while 40% have been using between 5 to 20 years. The complete results of the domain of context can be seen in Table 1.

Utility of the functionalities

Analyzing the functionalities, the results were the following (Table 2):

A. Functions of the EMR itself

To record or write progress notes: 95% found it useful or very useful, while only 1% disagreed and felt that this feature was not useful or useless.

Progress notes recorded with voice recognition: were evaluated as useful or very useful in 58% of cases and useless or unhelpful in 13% of cases.

Availability of a list of diagnoses of their patients in the EMR: was found to be useful or very useful by 96% of respondents.

B. Documentation functions

Ability to record laboratory results: was considered useful or very useful in 97%.

Recording of the images: was useful to 95% of the survey respondents.

Scanning and storage of physical documents in the EMR: was considered useful or very useful in 87%.

Documentation of patient vital signs: was at 88% useful or very useful.

Table 1 – Context characteristics of the users that answered the survey

Context	n	%
Male	3309	64
Average age (years)	47	
Years from certification:		
<10 years	1445	27
10-20 years	1186	23
>20 years	2353	47
Work in more than one place	3565	69
Workplace:		
Private	1444	28
Public	962	18
Both	2445	47
Use of electronic devices	3176	61
Use of health information system	2880	56
Which system:		
Digitizing	603	12
Scanning	134	3
In-house development	1606	31
Vendors development	509	10
Since when you use it:		
<5 years	1569	30
5-10 years	846	16
10-20 years	1186	23
>20 years	695	13
As regards the utilization:		
Useless/Little useful	36	0.7
Neutral	82	2
Useful/Very useful	4814	93
System deficiency:		
Slow	2110	41
Difficult	514	10
Unfriendly	1445	28
Do you receive support?	2103	40
How was the training:		
Virtual	465	9
Face to face	1103	21
Both	624	12
Others	1405	27
Non response	1574	30

C. Functions related to preventive care and decisions support

Warnings on recorded allergies of the patient: were found useful or very useful in 94% of cases.

Immunization record: was at 86% of the cases.

To receive reminders about the implementation of preventive practices: 87% of respondents found it useful or very useful.

Drug interactions warnings: this value was 91%.

D. Prescription and orders functions

Register usual medication: was useful or very useful in 96% of the time.

To consult recorded medication by others professionals: were 91% useful.

To record and print prescriptions: were considered useful or very useful for 85% of respondents.

E. Referrals related functions

To receive responses of the referrals professionals: 84% of respondents found useful or very useful.

F. Health education and access by patients (PHR)

Send reminders to patients by phone or mail: was evaluated as useful or very useful by 75%.

Allowing patients to access information about their histories, prior authorization by the professional permission: was considered useful or very useful 55% of the time, 25% of the professionals maintains a neutral position.

To create and print information and education programs for their patients: was found useful or very useful 84% of the time.

G. Administrative functions

Respondents rated as useful or very useful knowledge of the details of health insurance of their patients (75%), methods for allocating appointments (72%), the display of administrative information (66%) and the ability to search for patients according to certain characteristics for research studies (85%).

H. Interoperability

The professionals found the possibility of coding the diagnosis of their patients, as well as share registered information of their patients with other professionals very useful or useful in 83% of the time.

The 93% of respondents found useful or very useful to use informatics systems. When questioned about which system weaknesses you find most disturbing 40% said that the slowness, 28% to be unfriendly or less intuitive and 10% argued that the difficulty of use was the most glaring deficiency.

With regard to training and use: 41% of users of informatics systems have responded that count with technical support or assistance when needed. Regarding training, 9% did so in a virtual way, 21% face to face, 12% both ways, 27% used other methods of training and 30% did not answer this question.

As final answer, 60% of respondents said that would not still using paper records, while 28% prefer to continue using it. Finally 93% responded they would use EMR, while only 4% expressed as negative.

Discussion

While the survey had a large range and was answered by over 5000 people from more than 21 Spanish-speaking countries, we recognize the limitations of this study. It may be biased because the surveyed were users of a website which could be interpreted as an indirect indicator of their preference or ability to deal with software tools. In any case it was an interesting initial sample which analyzed EMR utilities for Latin-American health professionals.

Table 2 – Perception of the functionalities of the EMR

	Functionalities	Useless (%)	Little useful (%)	Neutral (%)	Useful (%)	Very useful (%)	NR (%)
A	Register / write progress notes	0,31	0,85	2,32	19,49	75,46	1,57
A	Possibility of register progress notes by voice recognition	4,45	8,88	25,51	21,95	36,2	3,02
A	Register the patient's diagnoses	0,19	0,25	1,37	18,66	77,63	1,9
B	Possibility of register laboratory results	0,12	0,37	1,12	18,58	78,8	1,01
B	Possibility of register image results	0,21	0,7	2,42	20,17	75,29	1,22
B	Possibility of scan and store data in the medical record	0,79	2,24	8,24	29,43	57,55	1,74
B	Register and review vital signs	0,68	1,8	7,54	31,04	57,05	1,9
C	Show warnings about allergies	0,23	0,5	3,35	21,74	72,23	1,95
C	Control the vaccines	0,7	1,64	9,21	32,66	53,01	2,78
C	Remind pending preventive practices	0,62	1,3	8,7	35	51,89	2,49
C	Receive alerts about pharmacological interactions	0,31	0,85	5,12	27,11	64,36	2,24
C	Send reminders by phone or e-mail	1,64	4,87	16,79	33,84	40,8	2,05
D	Register usual medication	0,17	0,21	1,9	25,45	70,61	1,66
D	Consult registered medication by other professionals	0,37	0,99	5,41	32,99	58,4	1,84
D	Register and print orders	0,93	2,15	9,19	30,44	54,52	2,78
E	Receive responses of the referrals	0,93	2,07	10,06	33,24	51,09	2,61
F	Allow your patients to see data of the medical record that you authorized	6,73	9,44	25,64	30,4	24,17	3,62
F	Create and print education programs and informartion for their patients	1,2	2,13	10,13	36,51	47,3	2,73
G	Access to coverage data	1,06	2,69	17,62	38,64	37,19	2,8
G	Make appointments	1,78	3,64	19,24	36,3	36,07	2,98
G	Possibility of view administrative information from other centers	2,03	4,8	23,26	32,22	34,15	3,54
G	To make paperwork fee	3,71	6,07	27,29	30,28	29,18	3,46
G	Search for patients by certain characteristics (protocols)	1,06	1,8	9,38	30,77	54,28	2,71
H	That the system encodes the diagnoses	1,14	2,63	10,95	28,06	55,06	2,17
H	Share data with colleagues	0,91	2,26	11,6	37,69	44,98	2,55

Regarding the context, there is a tendency in favor of males, which also can be observed for those with more than 20 years of graduation. More than half of respondents worked in more than one place, and most of them are in favor of the use of computer systems.

All the functionalities of the EMR, with the exception of the PHR and administrative applications, were categorized as useful or very useful with high values of acceptance.

The lowest values obtained were in the area of the PHR, which may be because it is a relatively new tool, little known, which raises security and confidentiality dilemmas still not entirely resolved. A deeper analysis will be necessary to explore these issues. This area also had high percentages in neutral rating.

The categories of the EMR functionalities such as progress notes or diagnosis registration, documentation and preventive care were the highest rated in the study.

With respect to the support and training, less than half of respondents stated that did not have support or assistance. A minority was trained virtually; overall there was a high rate of non-response for this particular question. There seemed to be some discrepancy between the usefulness of virtual training and the low values for these types of educational tools in this question.

In conclusion, our research has shown a consistently positive trend towards the use of EMR in the Latin American physician population. Further studies are required to more deeply explore the reasons for the slow dissemination and limited implementation in the field of health in Latin-American region, despite the fact that opinion surveys show high rates of agreement in favor of its usefulness.

How are clinicians involved in EHR planning? A process analysis case study of a region in Denmark

Anna Marie Høstgaard, Pernille Bertelsen, Christian Nøhr

Department of Development and Planning, Virtual Centre of Health Informatics, Aalborg University, 9220 Aalborg Ø, Denmark

Abstract

Experience shows that to achieve a successful implementation of EHR clinicians must obtain joint ownership of the decisions made during the EHR-process. The EHR planning process in the Region of North Jutland, Denmark was studied with the aim of answering the question; "Why are not all Danish physicians overjoyed by the introduction of EHR? A case study was carried out from Oct. 2003 till April 2006 using process analysis. The EHR project management's strategy meant that there was no workload reduction. This was seen as one of the main barriers for the physicians to achieve real influence. History shows that clinician's on the one hand and administrators on the other have different perceptions of the purpose of the patient record and that they both have struggled to influence this definition. To date, the administrators have won the battle. This was the major reason for the approach chosen for the EHR planning process in North Jutland, Denmark. It explains the conditions made available for the physicians, which led to their role being reduced to clinical consultants - rather than real participants.

Keywords:

Medical informatics, Hospital information systems, Planning techniques, Hospital organization and administration, Organizational decision making, Workload reduction.

Introduction

The Danish healthcare system is public and financed by taxes, and Danish hospitals are governed by the Danish Regions. In the last decade there has been extensive discussion about the electronic patient record (EHR) in Danish hospitals - among politicians, the administration and clinicians as well as in the media. Concurrent advances in information technology indicate that the EHR can be the solution to many of the problems associated with the paper based patient record, e.g. accessibility and data validity. As a result the Danish national strategy for IT in the healthcare sector published in 1999 [1] required all the Danish counties to implement an EHR. This caused the County of North Jutland (CNJ) to develop an overall IT-strategy [2]. In March 2004 a local EHR working group was set up to make the requirement specifications for the EHR and to choose between four possible systems.

However, experience has shown that the introduction of the EHR often brings with it a number of new problems, including some of an organizational nature [3-14]. Experience has also shown that for an EHR implementation to be successful the clinicians must obtain *positive clinical benefits* as a result of its implementation and *joint ownership* of the decisions made during the EHR-process. A prerequisite for joint ownership is *early* involvement of clinicians, the best possible *representation* of all groups of clinicians, giving the clinicians *real influence* in decision making and the possibility of *workload reduction* [4;15-18]. When it comes to development and implementation of EHR, experience shows that physicians are a very important group of clinicians because their acceptance is crucial to whether or not the EHR is brought into use in the intended way [19-24]. In this perspective, the research focus was on *physicians* as a relevant social EHR technology-carrier-group[1] in the EHR planning process at CNJ. Besides the physicians, IT-professionals and administrators were identified as significant social EHR technology carrier groups in the EHR planning process in CNJ.

Purpose

The purpose was to study *"Why are not all Danish physicians overjoyed by the introduction of EHR?"* by answering the following research questions:

Research questions

1. *Did the physicians have the necessary resources (interest, power, organization, information, access and knowledge) during the EHR planning process at CNJ to change their status from potential to actual social carriers of the EHR-technology?*
2. *Can the answer to the above research question be understood by studying the differing amounts of "meaning[2]" each of the relevant social groups, (physicians, IT-professionals and administrators), attached/attaches to the EHR?*

The new knowledge generated hereby will benefit both the continued development of the EHR process at CNJ and the future development and implementation of new technology in other Danish hospitals.

[1] A group of actors or a social entity which chooses the new technology and carries it forward towards the next phase in the process.

[2]Significance, goals, interests, needs (a concept used in the SCOT theory)

Theoretical framework

This research combines the Socio-technical carrier of technology theory [18;25-27] with the Social construction of technology theory (SCOT)[28].

In order to shed light on the interactions that occurred between the different relevant social groups during the planning process at CNJ (the *case* perspective) - i.e. within a relatively short timeframe - the Socio-technical carrier of technology theory was used. According to this theory, a new technology is chosen and carried forward in the technological development process by the actors or the social entities involved – the *social carriers of technology* - only if they have the necessary resources (interest, power, organization, information, access and knowledge) to change their status from being potential to *actual* social carriers of the technology. Every qualitative change in a technological development process can be traced back to a change in the *composition* of the social carriers of technology and in the conditions necessary to achieve the status of an *actual* social carrier of technology.

With a focus on physicians, this study was carried out at CNJ studying:

- The vested interests of the different relevant social carrier groups of technology in relation to the EHR
- Their options (power) to carry through these interests
- The degree of support from their professional association
- The amount of knowledge and information they had about EHR both in general and particularly regarding the different options available
- Their opportunities to see and test the system in practice (access).

The SCOT theory provided a framework for understanding the underlying reasons for the different social group's vested interests in the patient record - and the power they had or did not have to bring forward those interests. According to the SCOT theory, every stage in the development of a new technology involves choices between various options. Besides rather narrow, purely professional considerations, social factors (interests, power) determine what options are chosen. The *historical* perspective was, therefore, included in an attempt to uncover what "meaning" has been given by the different relevant social groups to the patient record from its origins in a paper format to the electronic format of today - in order to gain an understanding of the historical and current interests and the balance of power between the social groups.

Materials and Methods

Design

The study was designed as a case study with focus on a process orientated technology analysis of the EHR planning process in the County of North Jutland (CNJ) in Denmark. The research period was from Oct. 2003 till April 2006.

Population

In the *case* perspective, the relevant social groups were the physicians and IT-professionals in the EHR working group and the IT-Board of the county of North Jutland. In the *historical* perspective they were physicians and IT-professionals associated with the Danish hospital sector and hospital managers and EHR decision makers at regional level.

Data collection and analysis

Data were collected through:

- Observations at EHR working group meetings
- Interviews with 8 physicians (all) and 2 IT-professionals in the EHR working group and 2 members of the IT-Board
- Insight gathered from documents.

Data were analysed using the software programme ATLAS [29] with a focus on the six conditions to be a social carrier of EHR (interest, power, organization, information, access and knowledge) – and an "open mind" towards other themes.

The analysis was divided in two parts; a technology-carrier analysis for answering the first research question and a SCOT analysis for answering the second. Finally the initial question; *"Why are not all Danish physicians overjoyed by the introduction of EHR?"* was answered by a synthesis of the two analysis.

Trustworthiness

Trustworthiness was sought through data triangulation, approval of the transcripts by the interview persons and a thoroughly description of all activities throughout the process (transparency).

Results and analysis

Technology carrier analysis

All the physicians in the EHR-working group were asked to make requirement specifications for an EHR and to choose between four EHR systems. They expected *real* involvement in the EHR-planning process because of the nature of the tasks they were asked to carry out. The job implied a great deal of considerations, decision-making and choices during the process. Furthermore it required *true* involvement of all social groups for them to be able to reach agreements that included everyone's interests to the greatest extent possible. The EHR project management's strategy for the planning process led to the physicians *not* achieving *real* influence in the planning process. The predominantly informal planning strategy meant that there was no clinical work load reduction at all during the process. This was the main barrier for the physicians to achieve *true* involvement in the process, and it affected all six conditions - interest, power, organisation, information, access and knowledge - required to obtain the status of *actua*l social carriers of the EHR. Another serious barrier was that six of the eight physicians became members of the EHR working group eighteen months after the group was formed – and without any kind of pre-preparations prior to their enrolment. It meant that they – when it came to information and knowledge – were left far behind the other members of the group. None of the well

known prerequisites for obtaining joint ownership among users to decisions taken during an EHR processes were met during this EHR planning process. These are [4;15-18]:

- The best possible *representation* of all groups of clinicians
- *Early* involvement of clinicians
- *Real influence* in decision making
- The possibility of *workload reduction.*

The empirical data show that the EHR project management had underestimated the workload associated with the planning process. An interview with the project manager revealed that no attempts were made to learn from the experiences of management of EHR planning processes in other counties - including experiences about the need for workload reductions in one form or another. Besides the barriers for true involvement already mentioned the physicians did not have the necessary power, organizational support or knowledge to achieve *real* influence in the planning process or to *ensure* that clinical interests would be accommodated in the forthcoming EHR.

The Danish Medical Association was in no way involved in the process. The organizational support and encouragement that the physicians in the working group achieved during the planning process was given from colleagues at the main hospital in the region. Compared to the physicians the IT-professionals achieved much more power and organizational support. Their office (called "IT-Health") was in charge of the project management. At the same time, the director and the three heads of department at "IT-Health" were members of the IT-Board / the EHR Steering group respectively. Thus, the IT-professionals were part of the decision-making authority.

The physicians were specifically asked to concentrate on the *clinical* aspects of the EHR during the process. Because of the "dialogue based planning process[3]" the four systems became almost alike with respect to clinical aspects, and therefore clinical criteria were given up as criteria for selection of the system. The final choice of EHR system was then primarily made on the basis of the interests of the IT-professionals and the IT-Board, i.e. according to technical and economic criteria and not clinical criteria. The old saying; "knowledge is power" showed to be very true. The reality was; the more technical knowledge – the more power. Some of the physicians refused to chose between the systems before better information, access and knowledge about the systems was availably. That option was declined by the IT-Board, who had the power to make the final decisions. The physicians were - when it came to the possibility of *real* influence on which system to chose - powerless. Because of the working conditions they were given, their role in the process was reduced to the role of clinical consultants informing about physicians' needs in the requirement specifications and other documents. However, they were not able to fill this role completely because of lack of time. Therefore, also this work was to a large extent taken care of by IT-professionals from "IT-Health" with a past clinical background (not physicians).

A new way of carrying through the tender-process (part of the planning process) was used in CNJ; a "dialogue based process". It made dialogue between the members of the working group and the four vendors possible. The physicians felt that this made them able to gain insight in more aspects of the systems and to argument for their demands and wishes for the EHR. Because of the dialogue they succeeded in having a number of their demands written into the final contract requirements.

SCOT analysis

Internally Danish physicians form an inhomogeneous group with respect to their vision on both problems and solutions associated with the paper based patient record. They were therefore divided into two groups; "Clinical physicians" and "Frontrunners" by the researcher. Throughout the history of the patient record the two groups of physicians have had an *internal* struggle for the power and the right to define the purpose of this. The "Frontrunners" have through history advocated for the introduction of new versions based on visions of future clinical benefits – primary (clinical work) as well as secondary (teaching and research). The "Clinical physicians" have tried to "hold back" on this development, partly because they have felt no need for new versions, partly to "keep up" with daily clinical practice. However, in the long time perspective the "Clinical physicians" have always had to accept new - increasingly standardized - versions of the patient record. In the short-term perspective, however, more examples shows, that the "Clinical physicians" have succeeded in curbing the development for a time [19;23;30]. Because of a growing interest in the use of patient data for secondary non-clinical purposes (management and governance) among administrators and IT-professionals, the two groups of physicians have, however, recently taken a common *external* position when it comes to the *primary* purpose of patient data. This is as being for *primary clinical* use in daily clinical practice. Secondary clinical use - and other secondary purposes - must not compromise the primary use.

The Danish physicians have not only had an *internal* struggle throughout the history of the patient record for the power and the right to define the purpose of the patient record. Also an *external* struggle against administrators has been fought ever since the "birth" of the Danish patient record approximately 150 years ago. Administrators have historically shown a growing interest in patient records, because better possibilities to extract data for primary and secondary *clinical* purposes at the same time meant better possibilities to extract data for secondary *non-clinical* purposes. The development of the electronic health record was originally started by the "Front runners" with the *internal* control of treatment quality as its objective. This has over the years been taken over by administrators with *external* control of quality, efficiency and financing

[3] See explanation later

as its objective. At the same time, the argument about *patient safety* which for many years was used solely by physicians as an argument for using patient data for *clinical* purposes is now also used by administrators to legitimize the use of patient data for *non-clinical* purposes. The "Front runners" - and thus the medical profession - have in recent years lost most of the influence on the development of the patient record to the administrators, and the physicians' power and right to define the purpose of patient records appears today less than ever before.

Physicians and administrators have historically had and still have different understandings of the purpose of the patient record. Throughout history the two groups have fought for their *own* understanding whenever new versions of the record have been introduced. The planning process in the county of North Jutland, Denmark was an example showing this. Physicians here fought for their clinical interest against administrators and IT-professionals – the interests of the two latter groups to a large degree being the same. All three groups fought for the purpose of patient records to meet and support their *own* interests and work areas.

Conclusion

The answer to the first research question is on the basis of the technology analysis, that none of the conditions required in order to obtain the status of *actua*l social carriers of the EHR - interest, power, organisation, information, access and knowledge - were met for the physicians in the EHR working group. Their status as potential carriers of the EHR remained unchanged at the end of the planning process.

The answer to the second research question is on the basis of the SCOT analysis, that the different meanings the three social groups attach to the EHR are rooted in an inherited balance of power between physicians and administrators specifically. Ever since the "birth" of the Danish patient record, clinicians and the administrators have fought for the power and the right to define its purpose. Administrators have so far won this battle and seem to have a stronger position today than ever. This inherited battle of power was the major reason for the approach chosen for the planning process in the county of North Jutland. It is considered to be the reason for the conditions made available to the EHR working-group by the IT-Board during the planning process. Conditions that led to the role of physicians in the planning process in North Jutland being reduced to one of clinical consultants - rather than *real* participants.

The answer to the initial question; *"Why are not all Danish physicians overjoyed by the introduction of EHR?"* is that many physicians have bad experiences with technically immature systems or systems useless in the clinic but of greater benefit to administrators and economists. In addition, many physicians fear - based on bad experiences – that the medical profession will not gain *real* influence in the continued development of the electronic patient record. Physicians fear that this will result in records that do not provide positive clinical benefits but rather is a barrier to carrying out the daily clinical work. Many physicians therefore have a reluctant attitude towards new EHR development initiatives today.

Summary of findings

In order for physicians to be able to acquire joint ownership in the planning process a "dialogue based process" is recommended with:

- Work load reduction
- *Real* user involvement, *early* involvement and the best possible *representation* of users
- Working conditions that support *real* user involvement
- Sharing of past experiences at all levels (strategic, tactical and operational)
- Involvement of the Danish Medical Association, also at *County*/R*egional* level

Acknowledgments

I want to thank the County of North Jutland for taking part in financing this project and thereby making it possibly.

Abstract

Every single piece of healthcare information should be fully integrated and transparent within the electronic health record. The Italian Hospital of Buenos Aires initiated the project Multimedia Health Record with the goal to achieve this integration while maintaining a holistic view of current structure of the systems of the Hospital, where the axis remains are the patient and longitudinal history, commencing with section Computed Tomography. Was implemented DICOM standard for communication and image storage and bought a PACS. It was necessary adapt our generic reporting system for live up to the commercial RIS. The Computerized Tomography (CT) Scanners of our hospital were easily integrated into the DICOM network and all the CT Scans generated by our radiology service were stored in the PACS, reported using the Structured Reporting System (we installed diagnostic terminals equipped with 3 monitors) and displayed in the EHR at any point of HIBA's healthcare network.

Keywords:

Electronic medical records, PACS, Radiology information systems.

Introduction

In medical literature there are several definitions of medical records. The Institute of Medicine (IOM) defines it as the repository of information about a single patient, generated by health care professionals as a direct result of interaction with a patient or with individuals who have personal knowledge of the patient (or with both) [1]. According to Von Bemmel a medical record is "composed of findings, considerations, results of examinations and information about treatments followed in relation to the morbid process" [2]. Electronic Health Records (EHR) aren't outside these definitions. However, this last concept is more difficult to define. A large number of health organizations have information systems with different levels of development and integration, storing the information of clinical patients in different ways. The IOM defines EHR as a record that resides in a system specifically designed to support users by providing accessibility to complete and accurate data, alerts, reminders, clinical decision support systems, links to medical knowledge, and other aids [1].

On the other hand, images management and PACS (Picture Archiving and Communication Systems) development were conceived with the aim of achieving significant benefits for radiology departments, in terms of reducing film storage space needed and the staff's time, and ensure immediate access to the images. It is recognized that several of the major benefits of PACS is providing processed images and reports to physicians in a timely fashion. This improves care, facilitates clinical management and expands the capacity to conduct remote consultations [3]. The complete implementation of a PACS system has been often been an evolving process within a clinical institution with the concurrent evolution of hospital information systems with multimedia applications, facilitating images distribution [4]. And it also has been taking a growing interest in other areas which use diagnostic imaging, different to radiology, (e.g., cardiology, pathology, nuclear medicine).

Most centers that have implemented Healthcare Information Systems (HIS) and PACS, the latter was implemented in exclusively in radiology departments or in fewer cases in an integrated manner [5-7]. This way, most healthcare centers with HIS leave outside their clinical data repository (CDR) the multimedia elements, having them managed by stand alone applications, in an isolated way.

Ideally, the integration of this multimedia information must be fully and transparently with other CDR information. Thus, maintaining this integral approach, not looking forward to a separate repository for each service, but the professional been able to access multimedia information in the context of the patient's medical record, without changing application [8].

Then emerge the need for a Multimedia Health Record, in which the PACS in no longer a departmental component and becomes part of the storage system in which the CDR relies, and its information can be access in the context of the entire patient's information in the electronic medical record.

Objectives

Incorporate into our EHR the different studies that generate the various ancillary services in its original formats (images,

movies, audios, signals, etc.) beyond the text in the report.

Materials and Methods

Setting

The Hospital Italiano de Buenos Aires (HIBA) is a non-profit health care academic center founded in 1853, with over 1,500 physicians and 4000 employees. HIBA has a network of two hospitals with 750 beds (200 for intensive care), 500 home care patients under care, and 23 clinics. It has an insurance plan that covers approximately 150,000 people and also coordinates insurance for another 1,500,000 people who are covered by affiliated insurers. Each year over 38,000 inpatients (pediatric and adult) are admitted to its hospitals that are located in Buenos Aires and its suburban area. HIBA has more than 2,200,000 outpatient visits annually from patients from across the country and Latin America.

Since 1998, HIBA began to implement a Healthcare Information System (HIS) by coordinating clinical information with the administrative applications that were already in use [9-10]. It is an in-house project that currently handles all the information related to health care both clinical and administrative from capture to analysis.

All of our systems are web based, and among the most important components are:

- Electronic Health Record (EHR): is the access point to every piece of health information recorded in our healthcare network, as different GUI's for each level (ER, Inpatient, Ambulatory, Home Care, Day Hospital). It is problem-oriented and patient centered EHR system that includes a computerized provider order entry (CPOE) is available throughout the HIBA network.
- RPTGen: Generic Reporting System, transversal to the whole network. Is the Information System for each Ancillary Service, and also enables free text reporting. Its output is a CDA Document [11].
- Terminology Services: an interface vocabulary of our own, allowed us mapping of local vocabulary (thesaurus) to reference vocabulary SNOMED CT, and is in use by each of our applications [12].
- Master Patient Index, Scheduling System, Admissions, ADT, Intranet, among others

HIBA has used HL7 standards since 1999 [10]. Framed by the process of integrating the information systems for the EHR, Ancillary Services and Patient Services, the Department of Medical Informatics developed a document repository for clinical documents (consultation notes, discharge reports, etc.) and final reports from ancillary services, using HL7 and CDA documents to achieve full system interoperability.

Along with these developments it was necessary to incorporate desktops computers, not only in the development area and servers, but also through our entire healthcare network. Currently every point of care has a computer connected to the network, which can access de EHR and the rest of our applications; and there is more than 3000 point of care in our network.

The Radiology Department is a complex department, in many different locations inside the hospital because of its massive growing. It has over one hundred physicians (including residents) and other hundred and twenty healthcare professionals including technicians and nurses. Each month near 60.000 diagnostic procedures are performed, including MRI, CT scan, PET, US, X-Ray, Mammography, Angiography and Interventional Radiology.

Preliminary Stages

To ensure the success of this project, we developed a staged project management process. Each phase was well defined, resourced, and had the advantage of benefitting from strong administrative support.

Feasibility Study

In order to sustain support we elicited and defined institutional expectations with our planned objectives. During this feasibility period three major objectives redefined scope and project.

To achieve a complete and transparently integration of multimedia information it was necessary to maintain a holistic view of current systems in the hospital and specifically the electronic medical record and its interaction with the rest of systems. I.e., the multimedia component would be incorporated as any other piece of health information. But the main focus would remain the patient and his longitudinal record. We sought to avoid (as a concept) service independent repositories that would have increased physician workload.

In summary, we sought to provide professionals with seamless access to patient information within the context of clinical history without requiring a change of application.

Scope

It was necessary to define whether a service is in the scope of the project. This involved defining the departments that generates multimedia information whose inclusion into the EHR has clinical relevance. Taking into account national and international experiences, how they managed digital imaging and subsequent storage, and available standards.

It was also necessary to take into account the volume of each individual study and the organizational logistics that would present as a result of the change. We needed to explore workflow, equipment requirements –technical, physical, and ergonomic issues-. And, of course, our impact study dealt with the financial parameters.

Risks

As an extended project, it was necessary to take into account corporate and technological risk areas, scope redefinition, and changes, which would impact on the project from project inception to its implementation.

Equipment

It was necessary to make an inventory of equipment that generates clinical information in the form of images, audio, video, their ability to generate that information in an electronic manner to store it on the clinical record.

For each ancillary department we generated document detailing the inventory by hierarchical sub-area. This inventory was provided by the sector and completed by our team. In each group of teams was detail the possibility of issuing or receiving messages DICOM and its potential compatibility with the various types of messages [13].

Definitions

During 2006 our project team carried out surveys in each ancillary department. We decided to take the Radiology Department as our starting point, including the following sections: Computed Tomography, Radiology, Interventional Radiology, Digital Angiography, Positron Emission Tomography and Magnetic Resonance.

Ultrasound and mammography services were partially included in the project, because all administrative processes, technical and medical, including the report would change as the others, but without incorporating the images.

We decided to use the DICOM standard for communication and image storage, HL7 messaging which was already an institutional standard, and for administrative information a CDA standard (Clinical Documents Architecture) for reports [14-16].

All studies will be stored for an indefinite period of time, with lossless compression (without loss of information). Based on the analysis of the images generated by each section, we estimated that the storage needs for all Radiology Department would be 12 Terabytes per year. Is left out of the calculation the area of mammography, because the storage required only for this section is equivalent to all the rest of the project, the high cost of digital mammography devices and high definition monitor, besides its application is still somehow discussed among radiologists [17].

At last, some changes took place the radiological process to achieve the main objectives:

- Film less Service
- Reduce primary information in modalities, optimizing technology use and standards application.
- Change the reporting method, from traditional dictation to structured reporting.

With these definitions, we sought to reduce report turnaround time, which will allows faster access to the image by the referring physician.

Results

RIS

In spite of the fact that HIBA does not have a standalone Radiology Information System (RIS) its administrative functions are integrated within HIBA's HIS. Because of this, it was necessary to adapt our system of generic reports (RPTGen) to match the RIS commercial standards. Amendments were made in RPTGen for all involved. This included administration, technical, nursing, physician and systems professionals. This was done to reflect new or suggested post implementation processes for the Radiology Service.

At the same time we designed and developed a new structured reporting system, which output are CDA documents with coded entries and was integrated into the RPTGen.

PACS

Hardware

HIBA acquired an IBM System I server 570 (5 microprocessors Power 6), with a storage capacity of 40 Terabytes.

Software

We acquired a Picture Archive and Communication System (PACS) developed by the Spanish company UDIAT Center Diagnosis: RAIM. It enables a full integration with our systems and works with all required international standards.

Modalities

Through the different sections of the department we integrated DICOM (Digital Imaging and Communications in Medicine) modalities with our PACS network. Our aim was to make a full bidirectional integration including DICOM send, storage, print, modality work list (MWL), MPPS (modality performed procedure step):

- CT: we have five CT Scanners; three were able to make a seamless integration with the mentioned standards. An older device, just accepted DICOM storage and query & retrieve. And the oldest needed a "dicomizer" in order to perform DICOM SC (Secondary Capture).
- Radiology: we acquire a CR Solution with phosphorus chassis, seven single scanners and one multi scanner, with remote operation panels distributed near the most common image acquisition places (ICU, ER, Operating Rooms).
- Interventional and Dynamic Radiology and Digital Angiography were integrated using dicomizers.
- MRI: we have three scanners, all of them had a seamless integration with the mentioned standards.
- PET: one single Position Emission Tomography scanner fully integrated

Besides we were also able to successfully integrate most workstations. Following literature recommendations we decided to

install high resolution diagnostic terminals equipped with 3 monitors:

- Reporting Monitorss: 17-inch LCD screen with standard resolution for using the reporting system.
- Diagnostic Monitors: 2 monitors between 19 and 22 inches, four of them are three megapixels monochrome screens.

Communication

A network dedicated to the project, independent of the existing bi-LAN, with a category 6 cabling (1 gigabit per second) and category 7 inter-nodes. This DICOM network communicates PACS server with each DICOM node installed (modalities, workstations, terminals diagnostic, printers).

Integration

This is the key issue of the development of this project and the main purpose of it. The EHR is a gateway to all patient clinical information. Now, it includes the images and other multimedia information, accompanied by a report complying with the rules of the CDA standard, viewed from the EHR as all results of the studies generated by the Hospital, with the difference that includes a link to the corresponding images (Figure 1).

The installation of a PACS for managing digital images, the use of standards and modern systems used in the HIBA, helped seamlessly integrating systems described above. In this way, any image digitally generated by any of the mentioned modalities is automatically stored in our PACS and immediately creates an empty report in CDA (until the radiologist makes de definitive report) linking to the images. This web viewer is a Java application that requires minimal resources and runs on PC's with Windows OS from 98 to Vista.

Point of Departure and Current Status

At the conclusion of the stages of development and testing, it was decided to begin a pilot test in the Computed Tomography Section of our Radiology Department. After two months, we began wide spreading our implantation to the rest of the department, with a two months interval between sections. In year 2010 we will begin implementing other ancillary services: Pathology and Hemodynamic.

Discussion

There are recognized challenges of integrating the various modalities beyond DICOM Conformance Statement (especially those modalities of the past century); but this technical issues in most cases have a solution [18, 19].

A project of this magnitude implies a great deal of technological challenges (adequacy of internal networks, acquisition of the diagnostic stations to replace the negatoscopes, high availability systems, modernization of modalities, development and acquisition of software). It is also important to note some organizational challenges that have a high impact on the daily workflow of physicians in our institution. These include changes in the way of reporting for specialists (report dictation vs. direct reporting with structured systems).

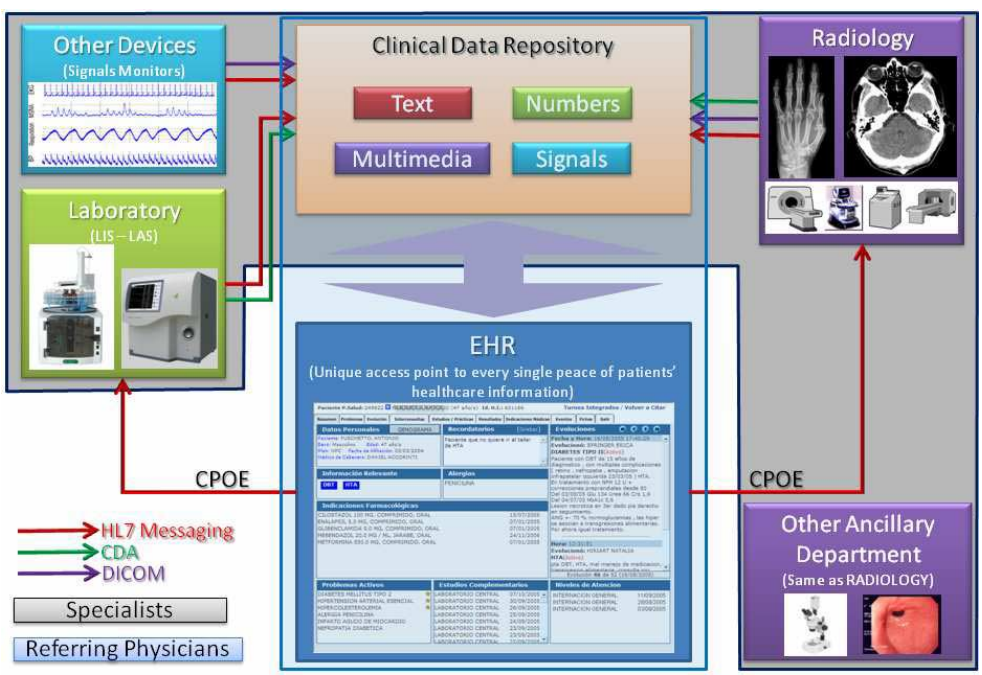

Figure 1 – Schema showing the EHR as the universal Access point to the clinical information for referring physicians

Despite the clear clinical and operational benefits of the project, clearly need to raise its economic justification. The savings would be generated by replacing image printing consumables and the improvement in the radiological process that will allow us to relocate 60 employees (typist).

Our filmless policy is not possible in all cases, depending which patient (outpatient, inpatient, etc..), the social security or medical program, type of study (radiography, ultrasound, mammography, ECG, etc..) and referring clinicians (HIBA, external, etc.).

Another economic aspect to investigate was the time in which, by legal or regulatory reasons, was necessary to store multimedia objects. In this aspect, technology improvements make storage costs dwindling, but it was necessary to define the cost per storage unit, to ensure feasibility over a period of time.

Conclusion

Taking into account our goals and the points outlined above, it is clear that, in our approach, a PACS is not a mere repository of images, but a documentary repository of multimedia elements in a Healthcare Information Systems setting, which provides data to the EHR. This is why the project is called "Multimedia Health Record" and not "PACS Project". And while making the Radiology Department as our starting point, the goal is to integrate all the ancillary services within this single repository, making a multidepartamental PACS.

The Avoidable Misfortune of a Computerized Patient Chart

Inger Dybdahl Sørby, Gry Seland, Øystein Nytrø

Department of Computer and Information Science, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

Abstract

The implementation of clinical information systems is demanding, particularly in hospitals, where reliable and well functioning information and communication tools are critical. In this paper we present different approaches to understanding and identifying challenges concerning the implementation of new electronic patient chart functionality. The context of the study was the development and implementation of the new system, which was withdrawn shortly after deployment in a medium-sized University Hospital. One year prior to the deployment we performed an observational study of current information and communication system usage in two hospital wards. Eight months later we conducted a usability test of the new functionality in a laboratory configured as a hospital ward. Four months after system deployment, the studies were followed up by interviews with healthcare personnel, members from the hospital implementation project group, and vendor representatives. The results of the studies show how the different approaches identify and reveal important issues that, if they had been taken into account, could have increased the chance of successful implementation of the system.

Keywords:

Clinical information systems, Observational study, Usability testing, System implementation.

Introduction

Several large Norwegian University Hospitals are in the process of implementing new patient chart functionality to be integrated with their existing electronic patient record (EPR) systems. The new functionality, which includes prescription and administration of medications, will replace central parts of current paper-based patient charts. Implementation of the new functionality into existing systems and clinical practices is an expensive, high risk process. Errors in the medication process might jeopardize patient safety, and usability problems of the system might lead to a disproportionate use of health care provider time on the system [1]. It is therefore crucial to reveal and realize potential risks and problems when designing the system and planning the implementation process.

In this paper we present different approaches to understanding and identifying the challenges related to deployment of new patient chart functionality in a Norwegian hospital. First, we present an observational study performed as an initial investigation of current information and communication system usage in two hospital wards. Secondly, we present results from a usability test of the new functionality conducted in a laboratory configured as a hospital ward. The studies were followed up by interviews conducted four months after deployment - and withdrawal - of the new functionality. Healthcare personnel, members from the system implementation project, and product owners from the vendor organization were interviewed. The findings and results from the interviews, the observational study, and the usability studies are summarized and discussed.

Background and Motivation

The patient chart - a collaboration and communication tool

The paper-based patient chart is a central collaboration and communication tool for health care personnel, particularly regarding medications. Physicians use the patient chart for prescribing medications, while nurses administer the medications to the patients and sign the same chart. The presentation of the patients' previous, current and administered medications gives both physicians and nurses a fairly good overview of each patient's medication status. In addition, the chart includes information about the patient's most recent laboratory and test results, and plans for further treatment [2].

Potential benefits of computerizing the patient chart (i.e. enhancing the quality and efficiency of health care and reducing the number of medication errors) are well recognized. It is the objective of both health record system developers and other healthcare stakeholders to replace the paper with a similarly efficient interface to the computerized patient record, and several attempts - however few successful - have been made to replace the paper-based chart with electronic versions.

Usability of Clinical IT Systems

Usability can be defined as the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use" [3]. In hospitals, the usability of the clinical systems is of particular importance. In the health industry, where the demands for effectiveness is increasing, the introduction of new technological solutions can potentially be lethal for the patients if the systems are poorly designed or if they are not tailored to the specific context of use in each hospital. For exam-

ple, Koppel et al. found a number of problems related to cumbersome medication charting and fragmented computer displays in a widely used commercial computerized physician order entry system [4]. Kjeldskov and colleagues found that usability problems may persist in time, as problems with an EPR system still remained after one year of extensive use [5]. Although usability testing is a well known and established method, it is a method that has to be adapted to the usage domain [6, 7].

Study Context

The focus of the study presented in this paper is the development and deployment of new patient chart functionality in a medium sized university hospital with 650 beds and approximately 5000 employees. Due to the complexity of the functionality and the workflow processes related to the chart, the new functionality was limited to medication issues, i.e. prescription and administration of medications. The new functionality was fully integrated with the existing EPR system.

The new functionality was deployed at the same time as the hospital moved to a brand new hospital building. The new locations implied organizational changes and new technical solutions. The new medication system was designed to function in the new hospital wards and with new routines for prescribing and administering medications. A brand new pharmacy automation system was intended to handle single-dosage medications prescribed via the new medication functionality in the EPR, and sending the medications by the pneumatic dispatch to the wards if they were available in the pharmacy automation system. The administration part of the system was intended for use with laptops on trolleys in the patient rooms. The system was integrated with bar code readers that could be used to identify patients and medications during drug administration.

Methods

The observational study was performed one year prior to the deployment of the new system. The usability study presented in the paper was conducted four months before the system deployment, and the follow-up interviews were performed four months after the system implementation and withdrawal.

Study 1: Structured Observations

Study 1 was performed to investigate and identify clinicians' information and communication behaviour in typical ward situations.

The approach is based on a previously developed method for performing structured observation of clinicians [8]. The observations were conducted by three senior medical students. The students performed non-participatory observations of physicians and nurses during various clinical situations, such as preround meetings, ward rounds, medication prescription and administration, and discharging patients.

The observers followed one main actor (i.e. a physician or a nurse) at a time. They recorded context information like situation type, trigger, co-actors, and roles, and sequences of information and communication acts. These sequences consisted of co-actors/information sources (e.g. colleagues, patient chart, patient record, EPR, physician's desk reference (PDR)) and information types (e.g. medication, diagnosis, findings and examination results). The data was recorded by means of paper forms consisting of both pre-defined codes and free-text fields, and subsequently transcribed to and processed in Microsoft Excel. The free-text fields would typically include explanations or the reason for choice of information source.

During the study, the observers spent a total of 24 days (appr. 150 hours) in two hospital wards, where patients with pulmonary diseases such as Chronic Obstructive Pulmonary Disease were treated. Six physicians (4 residents and 2 interns) and five nurses were followed. More than 3170 information and communication acts were recorded.

Findings – Observational study

Figure 1 shows how the distribution of the different information types the nurses and physicians used the paper-based patient chart to retrieve information about. The results show that nurses use the paper based patient chart mainly to retrieve information about medications (87,8 % of the time) and examination results (12,2 %). Physicians, on the other hand, review medication information in half of the cases (48,9 %), they review test and examination results in 45,6 % of the cases, and they also use the chart for other purposes like planning. This demonstrates that the physicians use the chart to get an overview of the patient and as a planning tool, including prescription of medications, while nurses mainly use the chart almost exclusively as an information source for administering medications.

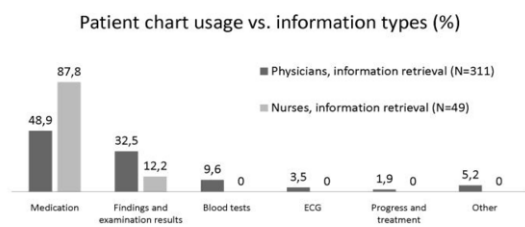

Figure 1 - Percentage distribution of patient chart usage

Figure 2 shows how the different information sources/systems are used by physicians and nurses to retrieve (upper part of figure) and to register (lower part) medication related information. The results further show that physicians use a wide variety of sources to inquire about medications: The paper-based chart (51 %), the patient (11,4 %), nurses (7,4 %), EPR (9,4 %), and the Physicians´ Desk Reference (PDR) (13,1 %). Nurses mainly use the chart (70,5 %) for information about medications, however physicians (21,3 %) and the EPR (6,6 %) are inquired as well. These results confirm the different tasks and information needs of different user groups like physicians and nurses. Physicians enquire different sources to get an overview of the patient's condition, confirm and re-check a

patient´s medication. Nurses use the chart when administering medications, and inquire physicians with questions about for example medication dosages. In addition to administering medication, nurses perform a control of the medications prescribed by questioning its correctness.

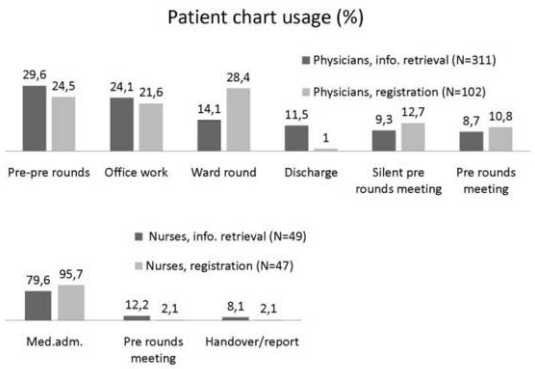

Figure 2 - Percentage distribution of medication related acts

Figure 3 shows how the patient chart is used in different situations by the physicians (upper part) and nurses (lower part). The results show that the nurses mainly use the chart when administering medications, while the physicians use the chart in several different clinical situations.

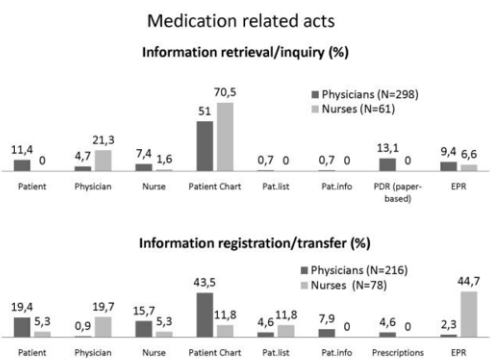

Figure 3 – Patient chart usage in different clinical situations

Study 2: Usability Testing of Patient Chart Functionality

The usability testing of the new EPR functionality was conducted during two one day workshops in a Usability Laboratory at The Norwegian EPR Research Centre. The usability laboratory is 80 square meters, and during the tests it was configured as a section of a hospital ward with two patient rooms, one office, and a hospital corridor. Video recordings of the participants and the system in use during the tests were done from the adjacent control room.

Two nurses and two physicians were recruited as test participants, three of them from the hospital deploying the new functionality. Health informatics researchers and two nurses from a local hospital acted as patients during the tests. Researchers functioned as facilitators, and one representative from the EPR system vendor was present at the second workshop. The vendor representative remained in the control room during the usability tests, but took part in the discussions following the tests. Data from two patient cases (personal, medication, physician and nurses' notes) were entered into the system prior to the tests, and the "patients" were instructed in their medical history.

During the tests, the physicians and nurses worked in pairs. They were instructed to perform their usual tasks during a preround meeting, a ward round, and medication administration, by means of the new chart functionality. The instructions were deliberately of little detail, in order to drive the scenarios by the medical problems in the patient cases. Prior to the test the participants were given a short introduction to the system, and after the tests there was a focus group discussion where the participants (including the "patients") summarized and discussed their experiences. The discussions were led by the facilitators. The tests and the discussions were captured on video for later analysis. After the focus group discussion of the second test, the participants could explore and test the system more informally, without the "patients" present.

Findings – Usability Test

A number of important usability issues were identified during the test and discussed in the debriefing sessions. The findings spanned from user interface problems to architectural issues and resulted in both suggestions for improvement of the system and recommendations related to the implementation process. The main findings are summarized below.

Lacking overview

The main problems revealed in the test were related to the lack of overview of the patients' medications. The physicians experienced that it was difficult to get an overview of the patient's current medications. Little space was given to the list of medications in the user interface of both the order entry part and the administration part, resulting in a lot of scrolling both horizontally and vertically in order to view important information.

Another problem perceived by the nurses was that when a medication was given to a patient and registered in the system with the bar code reader, the entry disappeared from the 'Current medications' list and re-appeared in the historic overview. The users found this little intuitive and cumbersome, as it was not immediately possible to see what medications the patient had been recently given.

Functionality problems

When the bar code reader was used, the system had to be set to ‘bar code reader mode’. This was perceived as an unstable system state, and the implication of the mode shift was difficult to understand.

Another problem occurred when one of the physicians wanted to stop a patient's medication for a short period of time. Since this function was placed in the medication administration

view, the physician was not able to locate it. However, the physician considered stopping a medication temporarily to be an order entry task, not a medication administration task, and the functionality should therefore be available in the order entry part of the system.

Implementation, training and use of the system

Some of the medication administration functionality was complicated, particularly related to the bar code reader. We therefore emphasized to the hospital that it was important that all nurses were trained in practical use of administration of medications using bar code reader, patient identification bracelet, and medications.

The medication user interface did not have separate menu choices for unexpected events, such as 'patient vomits drug'. There existed a general 'cancel' function, but the usage of the function appeared unclear in the usability test.

The results from the usability study were communicated to the hospital project group and the system vendor through a report. However, no changes in the system were made prior to the implementation.

Intermezzo: A Predictable Death?

The system tested in the usability laboratory was put into operation when the hospital moved to the new hospital building, but due to a number of problems during the start-up period, the system was withdrawn after a short period of use. The reported problems were related to among others logistic problems with deliveries of medications, organizational changes, and high workload in connection with the migration to the new buildings. However, the triggering factor was a protest from the physicians regarding lacking functionality and the poor usability of the system.

Post Mortem: Retrospective Interviews

In mature software engineering industry, it is common to gather, analyze and learn from projects by performing 'Post-mortem analysis' (PMA) [9, 10]. Such analysis includes gathering project metrics and evaluating performance, and is mainly performed as an internal exercise for the development team, who will be able to improve their practice in future projects. Users and stakeholders are normally not involved in the PMAs directly because the correspondence between a functionality or non-functionality of a system and the underlying development process is not always evident. In our study, however, we wanted to understand the reasons, from a user perspective, for the dismissal and rollback of the system. We therefore interviewed different stakeholders of the system: One nurse and two residents from the hospital where the system was deployed, two consultants from the hospital system implementation group, and two project leaders from the system vendor. The nurse and one of the physicians also participated in the usability test presented in this paper. The interviews with the nurse, the physicians, and the project leaders were individual, while the two consultants from the implementation group in the hospital were interviewed together.

The interviews lasted from 15 – 45 minutes and the main topics were 1: *What challenges were revealed through the methods described in this paper, and what challenges appeared at the hospital after system deployment,* and 2: *What were the main challenges when the system was in operation*?

According to one of the physicians, the main problems experienced with the user interface of the new system was the difficulty of getting an overview of the patients' medication status, medication actions, and changes.

One of the physicians also explained that they quite early decided to use the old paper chart in addition to the electronic system. When the system was in operation, they experienced that the nurses did not always administer the prescribed medications. A medication was not visible to a nurse if he or she opened the administration module shortly after the task was due. The result was that the patient was not given medication, accompanied by discussions about who were responsible for the mistake.

The interviewees also identified some major problems regarding medication delivery that affected the work of the nurses: the pharmacy automation system did not always deliver the ordered drugs; hence the nurses had to check the local storage, and possibly order the drugs from the pharmacy. They also experienced that medications were sent to wrong wards, due to a cumbersome routine for updating the EPR system. This caused delays and increased the workload of the physicians.

Results and Discussion

We are interested in whether the system rejection could have been predicted, or indicated, from the usability and observational studies. We have grouped findings from observations, usability tests and interview results into broad categories of issues, which can be summarized as belonging to lack of detail or content in different aspects of requirements, models, and implementation.

Information co-occurrence in user interface: whether information or functions that are needed together have high proximity in time or effort.

"The main problem was that it was difficult to get an overview of changes in the medication. (...)You ´open´ [a window for a] patient, who has been at the hospital for a few days, and have no idea about what has happened to the patient" (Resident 1)

This issue was discovered in the usability test, but became more salient when the system was deployed. From the observational study we found that physicians often review medication and examination information simultaneously.

Context of use: whether the different modes of use, user roles or usage situations are paid attention.

"The user interface was predominantly designed for nurses performing administration" (Resident 2)

Stopping a medication for a short period was only possible in the medicine administration interface (not used by physicians). Results from the observational study show that the physicians use the chart in a wide variety of clinical situations,

Interaction: whether the user interface is sufficient in ease of use and functionality.

"We are used to have a sheet of paper which states the patient's medication. It is not necessarily the right or the best solution, but it works to get a quick overview of the medications the patient has taken. If you have to move back and forth in four computer windows before you find the information, then you become unfocused. -- At least I do." (Nurse)

Work processes: whether variation, or uniformity, mishaps and deviation can be handled by the system.

The new chart functionality only supported medication prescription and administration, but no other tasks supported by the paper chart.

"You only understand the diagnosis when you see the paper chart. That overview was not possible in the IT system" (Resident 1)

This issue was identified in the usability test, but became a more obvious problem after system deployment. Data from the observational study show that physicians and nurses review medications and other information in the chart before prescribing and administration respectively.

In addition to these issues, other important issues identified in the analysis are related to temporality, work content, and collaboration

Could the misfortune of the patient chart have been avoided?

In this study both the usability test and the observational study indicated some of the major issues experienced after system deployment. Many of the problems pointed out in the interviews were indicated from test and observation findings. The findings from the observational study reflect the complexity of clinical work. In particular, they show how the patient chart is used in various clinical situations and contexts, and that the physicians use the chart for several other purposes than the nurses. It was therefore not a surprise that the physicians were less satisfied with the new system than the nurses, who mainly use the chart for medication administration. The usability test revealed the importance of getting an overview of the patients´ medications, which was also supported by the observational study.

The problems related to medication delivery and logistics issues were not identifiable in our studies, as they could only have been revealed by extensive testing of the entire system chain in the hospital.

Conclusions

Both studies presented in this paper pointed out crucial issues that, if they had been taken into account, could have increased the chance of successful deployment of the patient chart system. Usability laboratory tests reveal important and possibly problematic issues related to the user interface of the new system, while structured observations allow focused and quantitative grounding of use-cases, role models and stakeholder analysis. A combination of such methods is able to detect and elaborate on challenges, problems and discrepancies in a way that no single method can do.

Abstract

Misunderstandings due to terminology differences between health care providers and consumers may cause communication problems and adversely affect consumer access to health information, resulting in poor satisfaction for patients and providers. To investigate the usage patterns of consumer health vocabulary and evaluate controlled terminologies used in electronic medical records, we *conducted a usability study of patient-friendly terms used in an ambulatory electronic medical record (EMR) and associated patient web portal. After identifying 340 unique diagnosis term / patient- friendly term pairs, we mapped the term pairs determined by UMLS to be pairs of synonyms, near-synonyms, or closely-related terms to the keywords of search queries extracted from a consumer health information web portal to learn the comparative frequency of use of members of each pair by consumers. We found out that use of patient-friendly terms could help to bridge the language gap between providers and consumers but not always. In some cases the professional diagnosis terms were used more frequently than their patient-friendly counterparts, typically in cases where the professional terms were more simple or common than the patient-friendly terms.*

Keywords:

Terminology, Medical records, Internet, Patient access to records, Unified Medical Language System.

Introduction

There is a language gap between health care providers and consumers. Providers may not always familiar with medical terminology used by consumers. Likewise, consumers may not know the terminology used by providers. Misunderstandings due to terminology differences may cause communication problems and adversely affect consumer access to health information, resulting in poor satisfaction for patients and providers.

The differences between patients' and providers' expressions of medical concepts have long been recognized and studied [1-5]. The language gap between health care providers and consumers affecting health information retrieval has been studied in the fields of informatics [6-9]. Previous studies have demonstrated needs and efforts for bridging the language gap by developing consumer-friendly terminologies [10-18].

Zeng's research group has developed an open access and collaborative consumer health vocabulary initiative project. They identified 753 consumer terms and found the logistic regression model to be highly effective for term identification in strings derived from query logs of a consumer health site. In Zeng's logistic regression model, frequency of occurrence, string length, word count and number, frequency and termhood status, and nested strings are primarily used as variables, and the master vote as outcome[19]. In their previous study, Zeng's group developed a systematic methodology using corpus-based text analysis followed by human review to assign "consumer-friendly display names" to medical concepts from the UMLS Metathesaurus [20].

Plovnick and Zeng investigated the effect of reformulating consumer health queries using professional terminology [21]. They further developed a query suggestion tool called Health Information Query Assistant system to help consumers search for online health information. The system suggests alternative/additional query terms related to the user's initial query that can be used as building blocks to construct a better, more specific query [22].

Zhang and other researchers used a multidimensional scaling information visualization approach to examine user log files from a consumer health information web portal HealthLink. They investigated query searching behaviors and visually revealed groups of frequently used medical terms, and provided insight into semantic relationships among them [23]. Zhang's research group further employed an information visualization technique Self-Organizing Map (SOM) in combination with a new U-matrix algorithm to analyze health subject clusters through the HealthLink transaction log, which leads to a better understanding of the health-related topics and terminology from the users' traversal perspective [24]. While previous studies examined consumer-professional terminology difference either in health information retrieval or in the medical record, in our study we have explored the influences of the language gap in both areas and focused on the use of consumer terminology in an ambulatory EMR.

Since 2004, Froedtert Hospital and the Medical College of Wisconsin (MCW) have implemented an ambulatory electronic medical record EpicCare Ambulatory (Epic Systems Corporation, Madison WI). In 2008, an associated patient web portal MyChart® was implemented. MyChart® is the shared patient electronic health record integrated with the EpicCare Ambula-

tory EMR used by the healthcare team at Froedtert & MCW clinics. It gives patients controlled access to portions of their electronic medical record.

The EpicCare Ambulatory EMR incorporates a third-party medical vocabulary lexicon called Problem (IT)™ (Intelligent Medical Objects (IMO), Chicago, IL) Problem (IT)™ is a clinical diagnosis and problem list vocabulary containing specialized terms for clinicians, coders, and patients that links to ICD-9-CM. This lexicon enables an ICD-9-based controlled vocabulary to represent the descriptions that clinicians use when documenting diagnoses on the problems lists, or past medical history. Patient-friendly terms incorporated into Problem (IT) ™ are specifically designed for patient web portals like MyChart®. For example, a clinician may enter the clinical term 'Otorrhea' on a patients' problem list without needing to know the exact ICD-9 term or code (Unspecified Otorrhea 388.60). Likewise, a coder familiar with the ICD-9 code or term can specify either and locate the correct diagnosis. In EpicCare, providers can review and update the patients' problem list with clinical terms mapped via the IMO Lexicon. In MyChart®, patients see the patient-friendly terms associated with the diagnosis. In the previous example, when a clinician adds 'Otorrhea' to the problem list, the patient will see the associated patient-friendly terminology 'Drainage from the ear' in MyChart®. Quite often, the clinical term on the problem list is different than the patient-friendly terminology. These differences can lead to misinterpretations and confusion for both the patient and the provider, and can affect the quality of physician-patient interaction.

To investigate the usage patterns of consumer health vocabulary and evaluate controlled terminologies used in electronic medical records, we conducted a usability study of patient-friendly terms used in the EpicCare Ambulatory and MyChart®.

The study is significant because it:

1. Explores the different ways health care providers and consumers apprehend and express health concepts;
2. May improve communication between health care providers and consumers, assists consumers to better understand their health issues and helps them to find health information more efficiently with well-designed consumer-friendly terms;
3. May lead to a better understanding of health consumer information seeking behavior in terms of frequently used medical terms and associated terms;
4. May provide health information professionals with useful and first hand information that can be used to update and revise consumer health vocabularies.

Methods

First, we randomly chose fifty de-identified active MyChart® patients and analyzed the terminology differences between diagnosis terms on EpicCare and patient-friendly terms on MyChart® with same patient's health issues. Table 1 shows an example of the terminology differences.

Second, after removing duplicates, we identified 340 unique pairs of diagnosis term / patient-friendly term from the problem lists of fifty selected patients. We then employed UMLS to verify if the term pairs are exact match, synonyms, partial match or not match. We categorized those term pairs that are broader and narrower terms, related and possibly synonymous to be partial match. Of the 340 unique pairs, 18% diagnosis term / patient-friendly term pairs exactly match with each other, 28% are synonyms, 34% match partially, and 20% do not match with each other. Figure 1 shows the matching result of diagnosis term / patient-friendly term pairs.

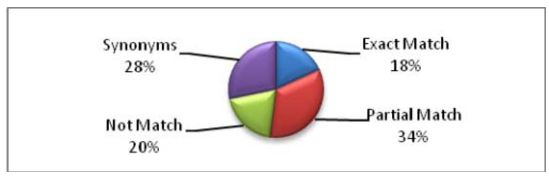

Figure 1 - Diagnosis term / patient-friendly term pairs matching result

Allergic Rhinitis, Cause Unspecified	DECREASED CIRCULATION IN FINGERS OR TOES
Barotrauma, Otitic	

Third, we manually mapped the term pairs that are not exact matches to UMLS to determine their relationship (synonym, near-synonym, closely-related, not-closely-related). For example, we mapped the diagnosis term / patient-friendly term pair "lateral epicondylitis of elbow / tennis elbow" to UMLS and determined they are synonyms in that they are assigned to the same concept unique identifier (CUI) "C0039516".

Forth, after excluding 67 pairs of not-closely-related terms, we mapped the remaining term pairs determined to be synonyms, near-synonyms, or closely-related terms to the keywords of search queries extracted from HealthLink transaction logs to determine the frequency of use by consumers.

HealthLink was an online consumer health resources dedicated to providing consumers with accurate and reliable health information. From 1998-2009, the HealthLink website provided current medical information in straightforward language that explains complex health issues in clear terms. The search terms from the HealthLink transaction log were used to determine the consumer-friendliness for either diagnosis terms or patient-friendly terms in Problem (IT) ™ in this study. These terms from the HealthLink transaction log were not indexing terms employed to index web pages in the HealthLink web portal. Instead, these terms were extracted from the queries submitted from consumers and were used to express a wide variety of customers' health information needs which include those raised from patient records and diagnoses.

Notice that there may be differences between patient-friendly terms in MyChart® and the search terms from the HealthLink transaction log. The primary purpose of patient-friendly terms in MyChart® is to help consumers understand the diagnoses described by these patient-friendly terms. It is natural to use these terms coming directly from consumers to measure the consumer-friendliness of either diagnosis terms or patient-friendly terms in Problem (IT) ™.

We expected that the more frequently the terms have been used for search, the more consumer-friendly the terms are. We chose synonyms, near-synonyms, and closely-related terms for analysis in order to focus on the different ways that health care providers and consumer express the same or similar medical concepts.

To do the mapping, we processed the raw web logs and extracted 3,091,980 search queries from three month's HealthLink transaction logs (October - December, 2008).

Results

Through UMLS, we identified 191 patient-friendly terms as synonyms, near-synonyms, or closely-related terms and their associated diagnosis terms.

Among 93 patient-friendly terms that are synonyms of their associated professional diagnosis terms, 19 of them were used more than 1,000 times in searches within HealthLink queries. 74 of them were searched less than 1,000 times. Table 2 shows the grouped frequency distribution of 93 searched patient-friendly terms that are synonyms of associated diagnosis terms. Among 98 patient-friendly terms that are nearly-synonyms and closely-related terms, 30 of them were used more than 100 times in HealthLink queries and 18 of them were used more than 1,000 times in three months.

Table 2 – Grouped frequency distribution of searched patient-friendly terms that are synonyms of diagnosis terms

Searching frequency	Occurring search terms	Percentage (%)
0-999	74	79.57
1000-1999	8	8.6
2000-2999	3	3.22
3000-3999	1	1.08
4000-4999	3	3.22
5000-5999	0	0
6000-6999	0	0
7000-7999	2	2.15
8000-8999	1	1.08
9000-9999	0	0
10000-11999	0	0
12000-12999	1	1.08
Total	93	100

For each pair of terms, we said that the term used more frequently than the second was more consumer-friendly. In most cases, patient-friendly terms received more searches and were thus more consumer-friendly. However, some diagnosis terms are more consumer-friendly than their associated patient-friendly terms. For example, "lipoma" received 2,166 searches while its associated patient-friendly term "fatty tumor" only got 16 searches. Meanwhile, the diagnosis term "allergy" received 5,601 searches and the assigned patient-friendly term "allergic reaction" only got 1,892 searches.

The most frequently searched patient-friendly term "obesity" was used 12,965 times in search queries over three months, while the associated diagnosis term "obese" was used only 982 times. 86 patiently-friendly terms were not used to search during the three months.

Table 3 shows the most frequently searched patient-friendly terms and their associated synonymous diagnosis terms. Table 4 shows the most frequently searched diagnosis terms and their associated synonymous patient-friendly terms.

These results show that the most frequently searched terms are usually single words or common words. Unlike health care providers who tend to use formal medical terms to describe health concepts, consumers use more simple words or "everyday language" to express those concepts. Sometimes, the professional terms are common enough to express health concepts, which are more frequently searched than so-called patient-friendly terms.

We found that the percentage of both synonyms (28%) and exact match (18%) is less than 50%. The low accuracy rate of the investigated vocabulary system (patient-friendly terms incorporated into Problem (IT) ™) suggests that these patient-friendly terms are not always helpful to narrow the terminology gap between the providers and patients. It shows that a further usability study is necessary and indispensable.

Table 3 - Most frequently searched patient-friendly terms and their associated diagnosis terms

Patient-Friendly Term	Frequency of HealthLink query	Diagnosis Term	Frequency of HealthLink query
obesity	12965	obese	982
diabetes	8447	diabetes mellitus	37
constipation	7445	unspecified constipation	0
high blood pressure	7189	hypertension	2902
urinary tract infection	5534	recurrent uti	23
rash	5005	rash and other nonspecific skin eruption	0
menopause	4984	asymptomatic postmenopausal status (age-related) (natural)	0
depression	4940	depressive disorder, not elsewhere classified	0
stroke	4406	cerebral vascular accident	0
kidney stone	4210	calculus of kidney	0
anemia	4003	unspecified anemia	0
heart disease	3851	unspecified heart disease	0
plantar fasciitis	2995	plantar fascial fibromatosis	0
epilepsy	2568	seizure disorder	97
asthma	2536	unspecified asthma	0
fatigue	2035	malaise and fatigue	0
allergic reaction	1892	allergy	5601
skin cancer	1825	basal cell carcinoma of skin	0
anxiety	1573	anxiety state, unspecified	0
migraine	1503	unspecified migraine without mention of intractable migraine	0

Table 4 - Most frequently searched diagnosis terms and their associated patient-friendly terms

Diagnosis Term	Frequency of HealthLink query	Patient-Friendly Term	Frequency of HealthLink query
gallstone	7766	gall stone	676
allergy	5601	allergic reaction	1892
lipoma	2166	fatty tumor	16
hypothyroid	1556	underactive thyroid	83
osteopenia	1393	bone disorder	0
neuropathy	1150	disorder of a single nerve	0
bph	700	enlarged prostate	0
edema	578	generalized swelling	0
lymphoma	535	malignant lymphoma	0
esophageal reflux	509	gastroesophageal reflux disease	346
hernia	452	abdominal hernia	0
coronary artery disease	403	heart disease due to blocked artery	0
eczema	342	allergic dermatitis	0
osteomalacia, unspecified	322	bone softening	0
varicose vein	197	varicose veins of legs	0
vocal cord paralysis	192	paralysis of vocal cords	3
ovarian cyst	174	cyst of ovary	0
attention deficit hyperactivity disorder	166	attention deficit disorder with hyperactivity	0
periodic limb movement disorder	153	periodic limb movement sleep disorder	0
sacroiliitis	90	sacroiliac inflammation	0

The findings of this study are based on 340 terms from the fifty de-identified patients' records from MyChart®. When the patient sample size increases, the number of the extracted terms will increase accordingly. As a result, the findings might be different. Notice that structure and coverage of a patient database also play a role in the final findings. If the same research method were applied to a different patient database, the results might be also different.

Conclusions

Health care professionals and consumers use different vocabularies to express health concepts. The use of patient-friendly terms could help to bridge the language gap but not always. If the professional terms are more simple or common than the assigned patient-friendly terms, they are more consumer-friendly. In this case, we should choose the same terms that professionals use instead of displaying the terms that are not really patient-friendly in order to avoid increased misunderstandings.

Abstract

Our electronic medical record (EMR) case study research pursued a set of questions to provide Canadian physicians with practical information on best practices and lessons learned regarding implementation and use of EMRs in ambulatory clinical care. The study's conceptual framework included an EMR System and Use Assessment Survey, interview guide, transcription codes, observation guide and case study report template. The common message that emerged was that no clinic would return to paper-based charts after experiencing the benefits of EMR. In seeking to corroborate our findings with success factors in an EMR implementation meta-framework, we further investigated the role of information incentives as a key factor in sustainable EMR implementations. The sections of our conceptual framework that best enabled us to capture information incentives were the 12 survey questions about information quality, EMR adoption questions in the interview guide and a subset of 26 items from our transcription coding scheme that were linked to physicians quotations about knowing more about the patient when using the EMR than when using paper.

Keywords:

Electronic medical records, Case studies, Motivation, Knowledge transfer, Boundary objects

Introduction

In our EMR study, clinics were invited to participate in case study research being conducted by researchers from across Canada. Participating clinics were selected on the basis of using their EMR as the sole clinical record, that is, as the computerized legal record of patient encounters. The study was sponsored by the Canadian Medical Association and was financially supported by Canada Health Infoway, a not-for-profit organization whose mandate is to accelerate the implementation of electronic health records across the country. These case studies represent the first time in Canada that a structured approach has been taken to examine the benefits of EMRs to primary care delivery.

The EHR Impact Study showed that an easy to operationalize concept of an electronic health record (EHR) system did not exist and a conceptual framework was needed to ensure comparability between different impact measures [1]. An EHR extends the concept of an EMR to include data sharing.

A conceptual framework was the common point of reference for the nine members of the research team who represented the different perspectives of clinician and health informatician. Content analysis in case study research requires methods and procedures that will increase the credibility and transferability of the knowledge that rises from using the conceptual framework. The framework served as a boundary object for building greater shared understanding. Boundary objects are artifacts that enable a common point of reference that can be shared by individuals with different perspectives (i.e. clinicians and health informaticians) [2].

When attempting to corroborate research results, one must reshape the data in ways that make it fit all the frameworks involved. According to an EMR implementation meta-framework analysis [3], the success-failure odds ratio for information incentives properly executed is 69.75 [4]. In seeking to corroborate our findings with this odds ratio, we start with our conceptual framework and determine which dimensions capture the information incentives that come "from the ability to know more about the patient when using the EMR than when using paper" [4, p.113].

Methods

The aim of this research study was to provide physicians with practical information on best practices and lessons learned regarding implementation and use of EMRs in ambulatory

clinical practices. To do this, we developed three primary research questions:

1. How are EMRs implemented?
2. How are EMRs used in clinical practice?
3. How can EMR adoption be increased and sustained?

The research consisted of two stages: the EMR System and Use Survey, which was used to tailor the subsequent interview; and a site visit comprising a one-hour interview with the lead physician and a series of one-hour observations of how the physician, nurse and office staff interacted with their EMR.

Conceptual Framework

The conceptual framework for the study included an EMR System and Use Assessment Survey, interview guide, transcription codes, observation guide and case study report template.

The 7-page EMR System and Use Assessment Survey posed 30 questions asking about overall user satisfaction: 8 questions asking about system quality; 12 questions asking about information quality; 7 questions asking about service quality; 6 questions that were population health specific; 9 questions asking about system usage; open-ended questions regarding EMR systems; and, 3 questions for demographic information.

The interview guide was designed to prompt for responses on implementation, managerial and organizational impact, EMR capabilities and use, EMR and patient care, EMR adoption, practice culture, patient feedback/experience, EMR cost/benefit and other comments. The consent form for the face-to-face interview sought permission for audio recording. The transcription of interview audio recordings was undertaken by an external transcription company. Interviews were conducted in English and French, and the French transcripts were sent to an external service for translation to English.

The 89-item transcription coding scheme was developed based on the research questions and the data. Each transcript was analyzed by two researchers: one was the interviewer; the second was another member of the research team. We used Atlas.ti, a qualitative analysis software program, to code transcribed data to concept categories. The two codings of each interview were done independently. Then the interviewer compared the two analyses and incorporated both perspectives to achieve the final coded interview [5].

The observation guide was used by the researcher to focus on the interactions with the EMR when shadowing the different members of the clinic staff. A set of questions were to be kept in mind: Who is using the EMR? When is the EMR used? What functions of the EMR are being used? Where is the EMR? How is the physician interacting with the patient while using the EMR? What are the strengths and weaknesses?

The researcher who completed the interview wrote up the case study report according to the case study report template. This template contained the following sections: executive summary, introduction, methodology, limitations and challenges of research, EMR capabilities and use, workflow and process changes, organizational impact (with subsections on workflow and clinical practice), key success factors, lessons learned, future plans, and, discussion and conclusions. Each case study report included a clinic sketch to show the physical configuration for encounters that involved patient, physician and computer screen [6].

Data Collection

The unit of analysis for these case studies was the clinical practice setting, rather than individuals, organizations, or the EMR system. Data was gathered from 20 clinics using previsit surveys, key informant interviews and observations.

Thematic Analysis

Using qualitative methods, we undertook a thematic analysis of data gathered from the site visits to answer our three research questions [7].

Filtering Conceptual Framework for Knowledge Transfer

We sought to corroborate specific findings from the EMR implementation meta-framework analysis [3,4] with our study as a means for knowledge transfer around the third question: How can EMR adoption be increased and sustained? The specific success factor chosen for a more in depth analysis was information incentives. This was chosen because the common message that emerged from our research was that no clinic would return to paper-based charts after experiencing the benefits of EMR.

The sections of our conceptual framework that best enabled us to capture information incentives were the 12 questions posed in the survey about information quality, questions in the interview guide on EMR adoption and a subset of 26 items from our 89-item transcription coding scheme that were linked to quotations that expressed how physicians were able to know more about the patient when using the EMR than when using paper

Results

Our nine member research team represented the different perspectives of clinician and health informatician. From a boundary object perspective, the conceptual framework provided a meeting ground among perspectives held by different participants in collaborative research. The only change to the conceptual framework after the research was underway was the addition of the concept of time to the transcription coding scheme.

Transcript coding analysis revealed variation in the application of the codes but convergence was achieved for common messages. Each interview was analyzed by two researchers to code transcribed data to a coding scheme based on 89 concept categories. Codes were developed based on the research questions and the data, and agreed upon by the research team. In total, researchers coded 3749 quotations from physician interviews for 20 EMR case studies.

The thematic analysis generated 20 themes loosely based on those pre-identified in the interview and observation guides [5]. These themes are listed in Table 1.

Table 1 – Themes across case studies

Theme	Theme
Clinic culture and leadership	Patient safety
Motivation	Key success factors and lessons learned
EMR capabilities and use	Barriers to EMR adoption
Technical issues	Benefits of EMR
Scanning	Facilitators of EMR adoption
Workflow and process change; Organization impact	Quality of care
Implementation strategy	Costs versus benefits
Productivity	Efficiency
Impact on patients	Lessons learned
Patient perspectives	Future plans

Success Factors

Clinics believed that their perceived time savings and improved patient record-keeping had improved the quality of care and patient safety by providing more complete information. These clinics used an integrated suite that contains clinical data as well as administrative data, rather than having separate business (back office) and clinical systems. This integration of clinical and administrative workflow is considered to be a key success factor.

Additional success factor topics in our study were categorized as: personal leadership and commitment to EMR; funding; change management and ability to re-engineer; payment model; and collaborative culture [5].

Classifications Across Two Conceptual Frameworks

We know from boundary object theory that classifications have their consequences [8]. When comparing our success factors with other literature we recognized a need to filter our conceptual framework to identify common concepts.

Keshavjee [4] used a different classification scheme to capture success factors in EMR implementation. These were expressed as governance; project leadership; involve stakeholders; choose software; sell benefits; pre-load/integration; tech usability; early planning; workflow redesign; implementation assistance; training; privacy & confidentiality; feedback and dialogue; support; user groups; incentives; and business continuity.

Our conceptual framework had to be adapted to enable us to corroborate what we revealed as success factors against Keshavjee's categories. The success-failure odds ratio is a metric that measures the importance of a factor in sustainable EMR implementations. As an example, incentives, which were primarily information incentives, had a success-failure odds ratio of 69.75.

We selected the concept of information incentives as a common concept worthy of further study. The definition of information incentives is the ability to know more about the patient using the EMR system than by using a paper-based system [4]. This concept can be conveyed in multiple ways. We explored how it was conveyed in the different components of our conceptual framework.

There were 14 items in the EMR System and Use Assessment Survey that explicitly addressed information quality. Improvement in information quality was reported in all clinics (12 strongly agree, 8 moderately agree). Most clinics felt that their EMR enabled the capture/recording of information that is accurate, consistent, complete, reliable, and with low risk of error to the patient. There was some disagreement on the completeness of the information recorded; this reflects the lack of interoperability with other systems. All clinics were content with the way in which their EMR presented information [5].

Of the 89 concept categories, we consider 26 as useful for capturing data on the information incentives, and give the number of quotations associated with the code in parentheses (Table 2). A review of associated quotes for the three most frequently used codes revealed the following ratios of positive to negative quotes: access to data 102:27; quality of care 94:4; interoperability 32:66.

Table 2 – Codes associated with information incentives

Item	Item
access to data (129)	patient education (55)
chronic disease management (62)	patient safety (33)
communicating patient information (63)	population health (33)
data mining (8)	practice management (39)
decision making (51)	productivity (41)
EHR (19)	professional development (28)
Email (8)	quality of care (98)
information flow (56)	recalls (21)
information resources (28)	referrals (27)
internal communication (33)	remote access (37)
interoperability (96)	requests for information (3)
motivation (60)	secondary analysis (4)
organization of data (41)	stewardship of data (14)

Information Incentives as a Success Factor

Respondents cited a set of benefits that outweighed the costs of EMRs. These included efficiency gains associated with EMR prescribing features; the ability to generate referrals; confidence in information and data; lab results; and accuracy. Those with electronic receipt of lab data believe that this feature in itself immediately improves patient care. Other improvements in quality of care arise from the simple fact that the chart is now legible, and the information can be used in

terms of proactive and preventative care. The EMR empowers physicians to provide quality care, because information is more easily available and the information is correct.

The following illustrative quotes came from physicians.

> *"Clinical notes that are legible, prescriptions that are integrated, alerts for drug interactions, renewal made easier, electronic receiving of labs that is very quick, in the minutes following its production, whereas before it could take up to two days to have access, when it was on paper, it's easier when a colleague is on maternity leave or sick leave, it's easier to communicate with other colleagues. When I have a note and I want to advise him, I send it in the internal messaging system and he receives the note in his inbox. That's what it's made easier, yes."*

> *"Clinics feel comfortable with their information — that it is always there, never lost, and most of all, always legible."*

> *"You can be confident in the information you're seeing. Not only is the note legible, another thing that improves care is that the notes — when you dictate notes, or when you're doing the notes firsthand, when you're right there with a patient — you put little nuances and implications into your notes that actually improve the care. Because you understand what you were thinking before, or you can understand what the other physician was thinking."*

> *"I believe it gives better patient care… I definitely think it's the way to practice. It's organized, it's neat, it's legible, and it facilitates communication with your office staff."*

> *"We use the Drug Interaction module. There's Clinical Support Decision Tools like Chronic Disease Management Guidelines and things like that."*

Information Incentives and Potential for Improvement

A few EMR functions were dependent on interoperability with external systems in hospitals, labs and other health providers. Insufficient interoperability was shown to be a significant roadblock to successful implementation. Policy makers would be wise to address interoperability issues in order to increase EMR adoption and sustainability.

> *"The lack of integration. The lack of big-picture vision of what electronic records are going to look like in …, and move systematically toward a big-picture integrated, functional system that it should be, given the day and age of IT."*

> *"One of the biggest issues right now is the continuing frustration that because of regulatory issues and readiness I can't just push out a prescription to the pharmacist. I have to print it and give it to the patient. I can't just message outside of my system very well."*

> *"It's an EMR practice in a paper-based system."*

The usability of EMR functions also impacts information incentives as a success factor.

> *"The main advantage of having an EMR is precisely that it integrates the clinical with the administrative. Because if you buy two different systems, I don't think it's necessarily a very bad decision, but you lose the advantages linked to integrating things together. But there are suites that have modules that are not as good — like the system we currently have, the scheduling, it's not as good as the one I had before. I gained on other things, I lost on some others".*

Many of the clinics have staff exclusively scanning paper documents received from other health care providers. This distracts from much of the potential cost savings predicted by many EMR vendors.

> *"I would say that we may even have more staff than we would if we weren't electronic just because we receive so much in paper copy and we're trying to get it into electronic form."*

Discussion

A conceptual framework was required for a diverse team of researchers to collaborate on case study research. The Canadian EMR Case Studies conceptual framework ensured that the research was conducted in a way that enabled the team to observe a number of commonalities across case studies.

The coding system designed for a particular set of research questions worked well for cross-case analysis, but required some pooling of concepts for comparison of research findings with another EMR implementation analysis study based on a different conceptual framework.

Complex behaviour change interventions, such as EMR implementation, require the use of consistent terminology to support meta-analyses and dissemination of scientific results [9]. The commonalities across the 20 case studies in our research identified the following success factors: personal leadership and commitment to EMR; funding; change management and ability to re-engineer; payment model; and collaborative culture [5]. Keshavjee's factors for EMR implementation success in his meta-analysis were: governance; project leadership; involve stakeholders; choose software; sell benefits; preload/integration; technology usability; early planning; workflow redesign; implementation assistance; training; privacy and confidentiality; feedback and dialogue; support; user groups; incentives; and business continuity [4].

The investigation into one specific success factor, information incentives, illustrated how issues around data organization and indexing need to be addressed to improve knowledge transfer. One resource that could help inform methods for head-to-head comparison of frameworks is the Rx for Change Interventions Database. It organizes its information according to the intervention classification scheme of the Effective Practice and Organisation of Care (EPOC) Review Group in the Cochrane Collaboration [10].

Conclusion

The common message that emerged from the research into how Canadian physicians are using EMRs in primary care delivery was that no clinic would return to paper-based charts after experiencing the benefits of EMR [5]. The attainment of a common message illustrates that the perspectives of the two decision-making cultures in EMR implementation—the clinician and the health informatician—converged. The conceptual framework served as a boundary object and enabled the research team to achieve a shared ground.

The vocabulary used to express success factors varied across studies and illustrated difficulties that could arise in pooling data across research studies. Further work is required to make commensurable the different ways that success factors are categorized in different studies.

Abstract

Systematic review authors synthesize research to guide clinicians in their practice of evidence-based medicine. Teammates independently identify provisionally eligible studies by reading the same set of hundreds and sometimes thousands of citations during an initial screening phase. We investigated whether supervised machine learning methods can potentially reduce their workload. We also extended earlier research by including observational studies of a rare condition. To build training and test sets, we used annotated citations from a search conducted for an in-progress Cochrane systematic review. We extracted features from titles, abstracts, and metadata, then trained, optimized, and tested several classifiers with respect to mean performance based on 10-fold cross-validations. In the training condition, the evolutionary support vector machine (EvoSVM) with an Epanechnikov or radial kernel is the best classifier: mean recall=100%; mean precision=48% and 41%, respectively. In the test condition, EvoSVM performance degrades: mean recall=77%, mean precision ranges from 26% to 37%. Because near-perfect recall is essential in this context, we conclude that supervised machine learning methods may be useful for reducing workload under certain conditions.

Introduction

We conducted this study to test the hypothesis that supervised machine learning methods can potentially reduce the workload of systematic reviewers during the initial screening phase of citations. In this phase, teammates independently identify provisionally eligible studies by reading the same set of hundreds and sometimes thousands of titles and abstracts (TIABS). This bottleneck slows the production of quality systematic reviews meant to synthesize research to guide clinicians in their practice of evidence-based medicine.

Additionally, we extended the work of Aphinyanophongs *et al.* [1], Cohen *et al.* [2], and Kilicoglu *et al.* [3] who sought to find rigorous clinical research using supervised machine learning methods. Based on the work of Haynes and colleagues (e.g., see [4]), rigor was presumed if trials comparing treatments were randomized and controlled.

To classify studies with respect to rigor or quality, each research group constructed a reference collection or 'gold standard' of positive cases. Aphinyaphongs and colleagues [1] used MEDLINE records for articles abstracted by the *ACP Journal Club*, which is a respected meta-journal that abstracts or cites evidence-based research in internal medicine for clinicians. Cohen *et al.* [2] used citations for randomized controlled trials (RCTs) included in 15 systematic reviews of drug therapies conducted by an Evidence-based Practice Center (EPC) funded by the US Agency for Healthcare Research and Quality. (The EPC files are publicly available at http://medir.ohsu.edu/~cohenaa/_systematic-drug-class-review-data.html.) Kilicoglu *et al.* [3] used a large subset of manually annotated citations for documents that were used to develop the clinical query filters in PubMed [4]. They selected rigorous studies relevant to human healthcare with a treatment or prevention focus as a gold standard.

Because randomized and quasi-randomized controlled trials (RCTs) tend to be less biased relative to nonrandomized and observational studies, review authors prefer to include RCTs and quasi-RCTs in their systematic reviews. However, it is sometimes necessary to include studies with weaker designs when RCTs are unlikely or unethical. For example, nonrandomized and observational studies are common for studies of: exposure to environmental hazards; invasive surgery compared to no surgery; risk factors for patients with chronic conditions; outcomes associated with patient-selected devices or over-the-counter drugs; diagnostic accuracy; and rare disorders. Thus, to meet the need for synthesized evidence for these kinds of questions, classification methods for studies with weaker designs should be developed along with those for RCTs.

The challenges are significant. Consider, for example, that abstracts with potentially informative words and phrases regarding trial or study design were unavailable in MEDLINE

for most articles published before 1976. Moreover, few terms for designs were available in the MeSH Thesaurus before the 1990s [5 (p. 131)]. Since then, terms have been added or modified to index designs, including weaker ones. For example, the term 'study characteristics [publication type]' includes narrower terms for 'case reports,' 'comparative study,' and 'evaluation studies.' Nevertheless, according to the Cochrane Non-Randomised Studies Methods Group, (1) authors of primary studies inconsistently describe the designs of their studies; (2) bibliographic databases do not reliably index designs; and (3) good filters for nonrandomized or observational studies do not yet exist [6]. In fact, when the latter are eligible for inclusion in a review, authors are enjoined to *not* include design terms in their search filters unless the retrieval set is so large that the review becomes impractical. Thus, the initial screening phase is typically labor intensive when both randomized trials and nonrandomized studies are eligible.

Methods

We used a recently approved search strategy for a Cochrane systematic review about ameloblastomas, which are rare odontogenic tumors of the jaws [7]. This strategy combines a topic filter with the Cochrane highly sensitive filter for identifying randomized controlled trials (see Box 6.4.c in [5]), and a modified SIGN filter for observational studies [8]. (Without terms for designs, the size of the initial retrieval set would have forestalled the review.) The combined filter is designed to find studies that compare surgical resection to any other treatment of ameloblastomas. The editors of the Cochrane Oral Health Group acknowledged the probable low incidence of ameloblastomas and therefore approved inclusion of case-control and patient registry studies. Because the primary outcome is recurrence of the tumor, Bekhuis and colleagues modified the SIGN filter by excluding cross-sectional studies and by including terms for registry studies [7].

The Cochrane Oral Health Group Trials Search Coordinator conducted the search, which yielded 1774 citations from four databases: MEDLINE, EMBASE, the Cochrane Central Register of Controlled Trials (CENTRAL), and the Cochrane Oral Health Group Trials Register. We also retrieved 41 citations from two systematic reviews [9, 10]. After de-duplication, the total number of citations was 1814. We sorted the corpus by publication date in descending order. Even though indexing may be inadequate with respect to design, the sorting reflects our belief that observational studies published after 2007 may be better described in titles and abstracts. This is partly because of the increasing adoption of the STROBE statement for reporting observational studies [11] by biomedical journals, including *Annals of Internal Medicine, Lancet,* and *PLoS,* among others. (See a list of journals at http://www.strobe-statement.org.) In the STROBE checklist, one of several recommendations for writing a good report states that authors should "indicate the study's design with a commonly used term in the title or the abstract." The checklist is available at http://www.strobe-statement.org/index.php?id=checklists.

We built training and test sets by selecting the most recent citations from the initial retrieval set and then proportionately distributed citations from the systematic reviews. Citations in the test set (n=100) and training set (n=300) were labeled with respect to eligibility status in accordance with the consensus decisions of the Cochrane review team [7]. Thus, citations pointing to provisionally eligible studies were labeled as 'include' and those pointing to ineligible studies as 'exclude.' Thirteen percent of studies (13%) were provisionally eligible in both the training and test sets.

We used EndNote to manage citations, to record eligibility decisions of the review team, and to export a text file of 400 citations which was then 'chunked' into separate files (one per citation) using Perl. We used RapidMiner [12], a software package for machine learning and data mining, to which we added a plug-in to process text (available at http://wvtool.sourceforge.net).

Features were extracted from TIABS and metadata using a bag-of-words approach. Pre-processing text involved string tokenizing, converting to lower case, filtering out Medline [13] or English stop words, filtering out tokens with length less than 3, and Porter stemming. Feature vectors were weighted with term frequencies (TF) or the product of TF and inverse document frequencies (TFIDF); vectors were pruned of terms that occurred in at most 3 citations. Features were selected for information gain.

Broadly, we followed the following steps: (1) We trained several classifiers using processed feature sets; (2) compared mean performance of classifiers based on 10-fold cross-validations, where performance measures were mean recall, mean precision, and the harmonic mean of equally-weighted precision and recall (F_1); (3) used grid optimization to find the kernel type that minimized absolute error for the evolutionary support vector machine (EvoSVM) classifier [14]; (4) investigated the impact of training set size on performance; and (5) compared the performance of EvoSVM configurations on the held-out test set.

Results

In early analyses, naïve Bayes and support vector machines (SVMs)—distinct from EvoSVMs—failed as classifiers, even though many researchers have used these algorithms to successfully classify documents [15]. Instead, we compared the following RapidMiner classifiers: DecisionTree, EvoSVM, and weightily averaged one-dependence estimator (WAODE) [16], focusing on EvoSVM in later analyses. To train the WAODE classifier, we first discretized features using the minimal entropy partitioning operator. Selected training results are presented in Table 1.

Analyses not presented compared the performance of each classifier by varying the weights (TF vs TFIDF) for the feature vectors. With the exception of the DecisionTree classifier, performance was better when using TFIDF weights. English stop words instead of MEDLINE stop words were used when pre-processing text for all classifiers because recall was higher when using the former in early analyses.

Table 1–Mean training performance of selected classifiers over 10-fold cross-validations

	Performance		
Classifier	**Mean Recall (%)**	**Mean Precision (%)**	**F_1**
DecisionTree (TF)			
MEDLINE Stop words	25.83	42.83	0.305
English Stop words	30.83	45.83	0.355
EvoSVM (TFIDF)			
Radial	100.00	41.47	0.578
Polynomial Degree 3	66.67	72.83	0.660
Polynomial Degree 4	65.83	73.50	0.676
Epanechnikov Degree 3	95.00	60.20	0.714
Epanechnikov Degree 4	100.00	48.29	0.648
WAODE (TFIDF)	65.83	72.33	0.677

In the training condition, recall is perfect for the EvoSVM classifier with a radial or Epanechnikov (degree 4) kernel, although precision is modest. F_1 is highest for the EvoSVM classifier with an Epanechnikov (degree 3) kernel (see Table 1).

Four EvoSVM kernel types (radial, Epanechnikov, Gaussian-combination, and multiquadric) were compared using a grid parameter optimization algorithm with 3 iterations over 10-fold cross-validations. The EvoSVM classifier with a radial kernel outperforms other configurations when considering absolute error, mean recall, and mean precision (see Table 2).

Table 2–Grid parameter optimization of EvoSVM kernel type (Complexity=1; sigma 1=10; TFIDF)

	Performance		
EvoSVM Kernel	**Absolute Error**	**Mean Recall (%)**	**Mean Precision (%)**
Radial	0.253	92.3	75.0
Epanechnikov	0.265	90.4	72.2
Gaussian-Combination	0.535	28.8	39.5
Multiquadric	0.393	50.0	43.3

When we trained the EvoSVM classifier with an Epanechnikov kernel (degree 4) on 150 citations instead of 300, mean recall degraded considerably, but precision and F_1 improved: mean recall=70.00%, mean precision=76.47% and F_1=0.72.

To understand the impact of training set size, we compared the corresponding feature set size for n_{train}=300, 250, 200, 150, and 100 (see Figure 1). We used stratified sampling to preserve the proportion of provisionally eligible studies in each sample.

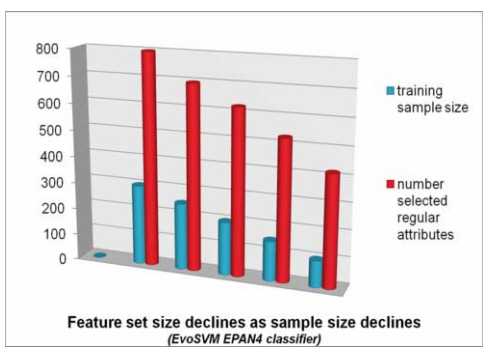

Figure 1–Feature set size is related to the number of citations in the training set.

We further investigated the relationship between performance of the EvoSVM classifier (Epanechnikov kernel, c=1, sigma1=10, TFIDF) and training set size. Training sets were again stratified. Mean recall degrades as the size of the training set decreases, dropping markedly when n_{train} =100; precision peaks when n_{train} =200 (see Figure 2).

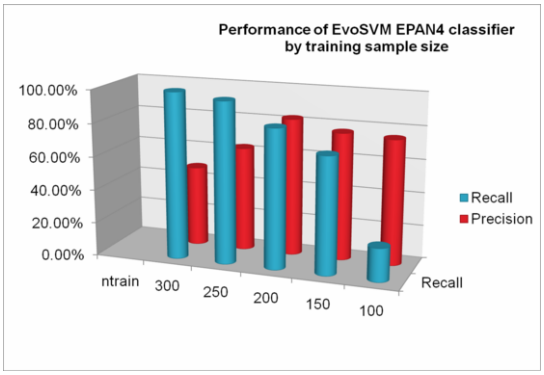

Figure 2–Performance of the EvoSVM classifier is related to the number of citations in the training set.

When we tested the EvoSVM classifier on the held-out test set of citations, performance degraded. Mean recall is equivalent for three configurations (77%), mean precision ranges from 26% to 37%, and F_1 from 0.39 to 0.50 (see Table 3).

Table 3–Performance of the EvoSVM classifier on the held-out test set of citations

	Performance		
EvoSVM Kernel	**Mean Recall (%)**	**Mean Precision (%)**	**F_1**
Radial	76.92	26.32	0.392
Epanechnikov Degree 3	76.92	37.04	0.500
Epanechnikov Degree 4	76.92	29.41	0.426

Note. Further analyses were conducted and the results are available upon request.

Discussion

It is important to realize that recall must be optimal for any machine learning approach meant to aid systematic review authors. For example, the Cochrane Collaboration strongly recommends broad and sensitive search strategies with high recall so that relevant research is not overlooked. In addition, review authors must make good-faith efforts to locate research missed by electronic searches. Thus, they handsearch journals, scan reference lists, contact subject experts, and more. This is why attaining very high recall is our primary goal. Boosting precision is a secondary goal even though modest precision is not as problematic as one might think when the percentage of provisionally eligible studies is relatively low. However, it may be a problem when the percentage is relatively high. Consider the following scenarios.

1. Assume that 2000 citations are retrieved, *10% point to provisionally eligible studies*, recall is perfect (100%), and precision is modest (50%). The classifier will correctly include 200 citations and incorrectly include another 200. The second review author of a two-member review team has to read 400 TIABS instead of 2000, which reduces her workload by 80%.
2. Same assumptions as before, except that *40% point to provisionally eligible studies*. The classifier will correctly include 800 citations and incorrectly include another 800. The second review author has to read 1600 citations, which reduces her workload by 20%.

Nevertheless, the absolute reduction of workload is probably more important to a human than the percent reduction. Consider, for example, that in the second scenario just posed, the review author is spared reading 400 TIABS even though her workload is reduced by just 20%.

Classifiers

In early analyses, the failure of naïve Bayes and support vector machine (SVM) classifiers—distinct from EvoSVMs—may have been due to violations of statistical assumptions. For example, naïve Bayes assumes independence of features and positional independence, and SVM assumes linearly separable classes. Because WAODE [16] and EvoSVM [14] classifiers relax these assumptions, they are more appropriate for these data. (The WAODE classifier differentially weights tree-augmented naïve Bayes models according to how informative each attribute is when set as the root of a tree. The EvoSVM classifier finds an optimal nonlinear hyperplane to classify data that are not linearly separable.)

Although we attained perfect recall with the EvoSVM classifier in the training condition and very high recall for EvoSVM with optimization, over fitting is still a concern. This concern was borne out in the held-out test condition when recall degraded. Nevertheless, the results are promising and suggest that EvoSVM with a radial or Epanechnikov kernel may be an appropriate classifier when observational studies are eligible for inclusion in a systematic review.

Limitations

This study has serious limitations. First, the extracted features may not have been representative of the domain because of the small size of the training set. This could account for the degradation of performance on the held-out test set. In the future, more than 1800 labeled citations from the initial screening phase of a Cochrane review [7] will be available. We expect that performance will improve when the classifiers are trained on a much larger set of citations than was the case for this study. Second, the bag-of-words approach—although affording an appropriate baseline—ignores important phrases, such as *case report, case series, literature review,* and *ameloblastomas of the jaws.* In the future, we will explore various feature sets to improve classification in the held-out testing phase. This will entail annotating citations for relevant terms and phrases, including design features and possibly affiliation and journal. Third, we know that stacking (a method of weighting several classifiers) is a promising approach [3, 17]. However, stacking probably works best with diverse feature sets and is therefore a method more appropriate for a

larger study. Finally, future evaluation of classifier performance needs to be statistically rigorous.

Conclusion

The evidence suggests that supervised machine learning methods can potentially reduce the workload of systematic review authors during the initial screening phase when (1) observational studies of treatments for a rare condition are eligible for inclusion in the review, (2) the proportion of provisionally eligible studies is relatively small, and (3) the number of citations is large enough to capture representative features.

Acknowledgments

This research was supported, in part, by the US National Library of Medicine (NLM) Research Participation Program, sponsored by NLM and administered by the Oak Ridge Institute for Science and Education; and by the NLM/NIDCR Pittsburgh Biomedical Informatics Training Program 5 T15 LM/DE07059-22. We would like to thank Mr. Halil Kilicoglu and Mr. Matthew Simpson for technical support; Drs. Thankam Thyvalikakath and Richard Oliver for help with labeling citations; and Ms. Anne Littlewood, Cochrane Oral Health Group Trials Search Coordinator, for conducting the search for citations.

Balancing centralised and decentralised EHR approaches to manage standardisation

Kirstine Hjære Rosenbeck, Anne Randorff Rasmussen, Pia Britt Elberg, Stig Kjær Andersen

[a] *Department of Health Science and Technology, Aalborg University, DK-9220 Aalborg Øst, Denmark*

Abstract

Balancing regional and national electronic health record (EHR) approaches requires cooperation between clinical and technical experts at different organisational levels. Bridging is necessary to achieve interoperability between regional EHR systems, without neglecting the clinical usefulness. This study has investigated the approaches chosen in modelling the clinical content of EHRs in two out of five regions in Denmark. Based on the knowledge obtained in these studies a 'clinical content format' was developed to facilitate the work of the regions, where the clinical content of EHR systems is modelled. The objective of the clinical content format is to enable share and reuse across organisations, furthermore an objective is to gradually introduce standards. The results of the first iteration of a 'clinical content format' are presented and future adjustments are discussed based on the results.

Keywords:

Computerized Medical Record Systems/standards, Computerized Medical Record Systems/administration and organisation

Introduction

In research communities, semantic interoperability is seen as a key to solving the problem of availability and timeliness of relevant clinical data. Semantic interoperability should make it possible to support shared care seamlessly [1] and reduce repeated data entry [2]. In order to achieve semantic interoperability in health care, several standardisation organisations, such as HL7, CEN, ISO, openEHR and IHTSDO, have formulated standardised information models and reference terminologies.[3] The vision of semantic interoperability, however, can not be achieved without a coordinated implementation of standards in nationwide and local eHealth initiatives.

A coordinated approach faces numerous obstacles. A 2007 EU Commission report was reviewing the eHealth status of eight European countries, Australia, Canada and USA. Here it was pointed out, that in all countries there was limited progress towards full semantic interoperability and a growing realisation that implementation of interoperable eHealth solutions will require years to set up. Also at the organisational level, the report concludes that the different national levels of centralisation and decentralisation should be taken into account. To help in coordination efforts, all countries have established or are planning to establish eHealth bodies. [4]

As illustrated in Figure 1, a national eHealth body task is the formulation of standards and strategies. The standards and strategies should be generic in order to support nationwide implementation, and should possibly be coordinated internationally. In decentralised eHealth initiatives, commercial applications are purchased and implemented. In the decentralised setup the priority is to keep the initiatives manageable. Thus, there is a contradiction between different organisational levels involved in e-health development.

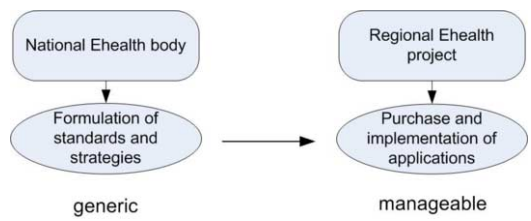

Figure 1 - National eHealth body and regional eHealth projects

In order to further explore the different organisational levels of eHealth, initiatives having both national and regional attention should be studied. Here we have chosen to focus on clinical content modelling in Danish EHR projects, since the scenario presented in Figure 1 is a reality.

National initiatives concerning the structure of EHR content are ongoing in auspices of the Danish eHealth body, Connected Digital Health in Denmark (Connected Health). The initiatives include:

- SNOMED CT has been translated to Danish, which is an important prerequisite in achieving semantic interoperability.
- Several times a year national workshops are held, where regional level actors, who implements the wishes and demands from users in EHR systems, meet. The purpose is to set the framework for exchange of experience early in development.

These are ambitious national initiatives in a small country. However, the initiatives are not trivial to implement since there

is a wide diversity of EHR systems and related IT-systems in the five Danish regions. When the regions implement EHR systems, they prioritise fast solutions that involve users' demands, and the national need to share information across regions becomes secondary. Thus, in the future it will be beneficial to implement standards in regional solutions, but right now specific regional business needs are lacking. Therefore this study addresses how to motivate implementation of national standards such as SNOMED CT in regional EHR projects.

Formalisation of clinical content in EHR projects

Clinical content is defined as the clinical knowledge built into EHR systems, expressed as domain-specific terms, rules and structures.[5]

Clinical content has several objectives:

- To define the interface terminology and relation between interface terminology and a standardised clinical terminology, such as SNOMED CT.
- To define the constraints in the input to EHR systems; e.g., to define a diastolic blood pressure as a number within a certain range.
- To structure the GUI of EHR systems, in order to support a certain clinical workflow.

Clinical content modelling is quite similar to the term 'knowledge level modelling' as described by Beale. Beale describes a two-level modelling approach, where the knowledge level requires its own formalism and structure, and is the level where the numerous, volatile concepts of most domains are expressed.[6] However, clinical content does not have a nationally agreed upon formalism and structure; therefore, and as a result of the decentralisation of EHR implementation, there are variations in the way clinical content is modelled. Thus, it becomes problematic to share and re-use clinical content across organisational borders. This causes each regional unit to commence its own clinical content projects from scratch, a process which is time-consuming and costly. National standardisation could possibly help to solve the problem. This study examines how a structure and formalism for clinical content, called a 'clinical content format', could be developed so as to support standardisation and manageability in a regional context.

Materials and Methods

Given the growing realisation that interoperability can not be rushed, iteratively improving a clinical content format in terms of standardisation could be part of a solution. The basic idea of the proposed method is that standardisation should be gradually introduced to ensure regional manageability.

Method overview

The method is inspired by Hevner et al., whose approach involves both analysis of business needs and knowledge resulting from research to develop innovative solution in the field of information system research. [7] The method developed is illustrated in Figure 2.

The analysis consists of two activities. The first is that of identifying the 'granulation level' in the current clinical content projects. Granulation level refers to the granulation of the material currently used to specify Clinical Content e.g. how entry names, formal representation for data-types and setup parameters of the EHR are defined. An analysis of the granulation level should ensure that the clinical content format is recognisable to the users, that it meets their needs and is manageable enough so that it can be used in practice. Granulation level analysis corresponds to Hevner et al.'s analysis of business needs.[7]

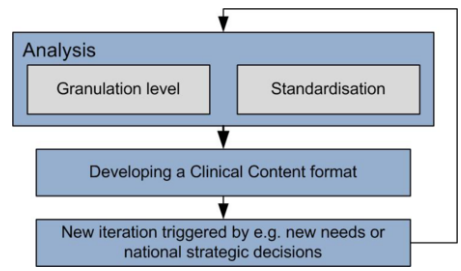

Figure 2 - Method used to develop a clinical content format.

The second activity, Analysis of standardisation, comprises identification of relevant EHR standards and selecting a subset of these based on available strategic decisions and the possibility of articulating clear gains for users. The chosen standardisation approach is integrated into the clinical content format. Analysis of standardisation corresponds to Hevner et al.'s examination of available knowledge resulting from research. [7] Whether standardisation belongs to the research base is an open question, but we regard it as such, since standardisation is widely discussed in the EHR research field. Thus, in the analysis regional needs and national goals of standardisation are balanced.

Based on the analysis, the clinical content format can be developed. Since the field of EHR projects and the standards are constantly changing, the clinical content format should be updated based on results of evaluation, new needs or national strategic decisions. Parallels can be drawn to Hevner et al., who include a number of 'assess' and 'refine' steps to iteratively improve developed solutions.[7]

The method is applied to clinical content modelling in Danish EHR projects as described in the introduction. Details are described in the next section.

Application of method

Granulation level analysis was conducted by examining clinical content projects in two out of the five Danish regions. The analysis included a study of public available information and semi-structured interviews with personnel in the organisations. The Capital Regions clinical content project[1] and the EHR implementation project at Odense University Hospital[2], were chosen as cases based on years of experience with clinical content modelling. The interviews were conducted according to the

[1] http://www.regionh.dk/menu/sundhedOghospitaler/SFI/
[2] http://www.epj.dk/wm122413

method described by Kvale [8]. Three OUH representatives and four Capital Region representatives were interviewed, resulting in 4 hours of recorded data, which was subsequently transcribed.

Relevant EHR standards in a clinical content context were identified by studying research literature (e.g. [3]). The subset to implement in the clinical content format was chosen on the basis of published Danish strategic decisions. Furthermore the possibility of regional adoption of the chosen standards were analysed based on afore mentioned interviews.

After defining the granulation level and the standardisation, the clinical content format was developed using UML class diagrams. The format was visualised in a Mock-Up GUI for developing clinical content, as the Mock-Up GUI provides an intuitive impression of possibilities and limitations of the clinical content format.

The clinical content format was evaluated by means of a presentation for a collection of regional and national actors in the field of clinical content under Connected Health auspices and followed up by an interview with a central Connected Health representative. The application of the method did not include the 'new iteration' step, but the discussion includes ideas about future use of the method as well as the developed clinical content format.

Results

This section consists of the results of the analysis, identifying the clinical content granulation level in the Capital Region and Odense University Hospital (OUH) and the results regarding standardisation. This is followed by a presentation of the developed clinical content format.

Analysis of granulation level

At OUH, the clinical content is modelled in order to enable configuration of the local EHR system, Cambio COSMIC™.[3] The clinical content is modelled through a cooperative arrangement between the hospital departments and a specialised team in the IT-department. The result is visualised in Word-templates. These are used when configuring the EHR system. From the OUH Word-templates, the clinical content granulation level can be deduced. The documentation (input) is most notable at OUH, since overviews of patient data (output) are system-dependent. The hospital departments started using the EHR system in practice as soon as the clinical content was implemented. In the Capital Region, formulation of clinical content is centralised in order to harmonise important documentation and overviews of patient data. The data structure is modelled using an openEHR archetype editor, without modelling real openEHR archetypes, since formal requirements of generic max-datasets are not satisfied. In addition, Mock-Up GUIs are produced in order to visualise both input and output screens. Free text descriptions are also included. These three clinical content information sources are vendor-independent. At present, however, the clinical content is implemented in Opus Arbejdsplads™ from CSC Scandihealth.[4] The implemented clinical content is not yet in routine use in any of the 14 hospitals in the Capital Region.

On the basis of an analysis of the Clinical Content in OUH and the Capitol Region the granulation level of the Clinical Content appears compatible. In short, the result can be expressed in following statements, defining the clinical content format:

- Input is described with setup parameters; e.g., a numeric field has the setup parameter 'unit'.
- Output is described with setup parameters; e.g., a description of the data source.
- The structure of a GUI using the clinical content is defined by an ordering of input and output fields.

Based on these observations the clinical content format can define a delimited and ordered collection of input and output fields with intended use in a specified clinical context. This granulation level limits the possible amount of information provided by the clinical content format since advanced functionality such as decision support cannot be implemented in this simple model. The simplicity reflects the current needs and support manageability, since the details that are defined are limited to those that are currently needed.

Analysis of standardisation

Standardisation of EHR system models and terminology is identified as prerequisites to obtain semantic interoperability.[9]

In Denmark, a strategic decision has been made to use SNOMED CT as common terminology. It is likely that users of the clinical content format could be convinced to map to SNOMED CT to avoid that each organisation is inventing its own terminology, for the GUIs for example. Regardless of whether standardised EHR system models are implemented in the future or message-based interoperability is continued, a prerequisite for sharing data is that the terminology is unambiguous. For the clinical content format, we analysed, that it would be manageable to use SNOMED CT for classification and indexing purposes. Indexing refers to labelling an input or output field with a SNOMED CT code, while classification refers to the selection of one code from a SNOMED CT subset. This simple implementation of the terminology will not facilitate all the possible applications of SNOMED CT. For example, free text is not translated into SNOMED CT concepts. As for the analysis of granulation level, this means that defined details are limited to those that are currently needed

When identifying standardised EHR system models, our conclusion was that since HL7 v. 3 and openEHR/ CEN16303 standards included a dual modelling approach[3], these could be feasible in the definition of clinical content. The clear gains for users of the Clinical Content format, however, remain unclear, since the EHR systems in use are based upon proprietary information models. In Denmark, no strategic decisions are made regarding use of any of these international standards.

[3] http://www.cambiosys.com/

[4] http://www.scandihealth.dk/

Therefore, the use of these standards is not explored in this first iteration on a clinical content format.

Clinical content format

The clinical content format, suggested based on the two cases, is illustrated in a simplified model in Figure 3. The *Specification* class contains the ID of a clinical content specification, e.g., the purpose, such as nutrition screening and the organisation, for example OUH. A *Specification* contains a *Structure Element* for each input and output field. The *hierarchy* attribute defines the placement of the field on the GUI. A *Structure Element* can be either an *Input* or an *Output* field, with added *setup* parameters. A *Structure Element* also contains *Terminology* that allows each field to be indexed using SNOMED CT. A specialisation of the *Input* class is *List.* The list allows the user to choose between several alternatives, when connected to the *Terminology* class. This allows for the use of SNOMED CT for classification purposes.

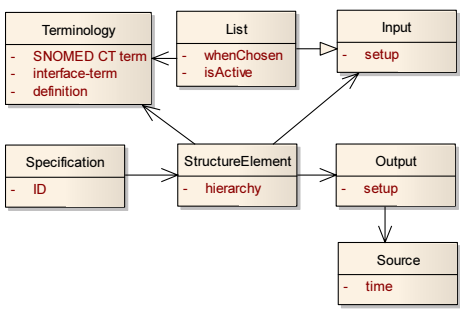

Figure 3 - Simplified clinical content format.

A detailed definition of the format is formulated but not described in this paper. The format is visualised by a Mock-Up GUI for developing clinical content. This is presented in Figure 4. The general idea is that input and output elements from the right side of the GUI can be brought into a hierarchy denoted by 1 and 2. Here interface terminology, SNOMED CT codes and field definition can be added.

When presenting this clinical content development tool, for potential users under Connected Health auspices, it was found that the overall objective of both meeting user's needs and introducing standardisation was considered complex and unexplored. The complexity is discussed in the next section.

Discussion

This study illustrates how a national clinical content format can be developed that balances both regional needs and national goals of standardisation. Hence, the developed approach can be used to facilitate share and re-use of clinical content. As described in the section on Method, future development and iterations of the clinical content format are intended to gradually introduce standardisation to enable a higher degree of interoperability. The complexity of this task, however, should not be underestimated, since factors other than clinical content modelling should be taken into account.

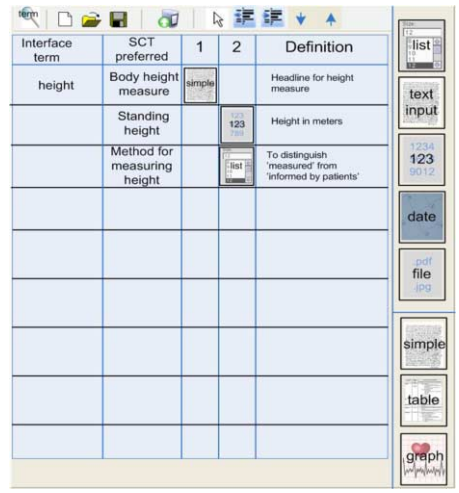

Figure 4- GUI presenting the possibilities of the clinical content format

In Figure 5, clinical content is bridging the technologically-oriented and clinically-oriented aspects. Clinical content should reflect clinical practice; for example, it should support the workflows and support clinical documentation. The long-term goal, however, is clinical standardisation. The purpose of clinical standardisation is to support evidence-based guidelines, to have standardised terminology and practice across organisational boundaries and to be able to document the clinical quality. Another aspect to be taken into account is the status of the currently available models and systems. The existing models and systems impose limits on the kind of clinical content that can be configured and the potential degree of interoperability. The long-term goal is to implement international EHR standards including reference terminologies, hereby enabling fully semantic interoperability. To improve health care delivery, cooperation is needed and multiple aspects should be taken into account; this is illustrated in the following example.

'At hospital A, they have improved the diabetes care by reviewing the clinical guidelines and incorporating them into their practice. While doing this, clinical content modelling was included. A national clinical content format was used as well as the proprietary format of the local EHR system. Expression of the clinical content in the national format enables hospital B to start a similar diabetes care. Thus, A and B carry out the same treatment and collect the same data; therefore they could compare the quality of their respective care or conduct clinical research. However, their vendors should make exchange of relevant data possible which is solved by introducing technical standardisation. After a while A and B decide, that they want to improve the structure of their documentation in order to enhance the documented quality of care. This leads to another

cycle of implementing clinical content, further refinement and improvement of the technical standardisation and so on.'

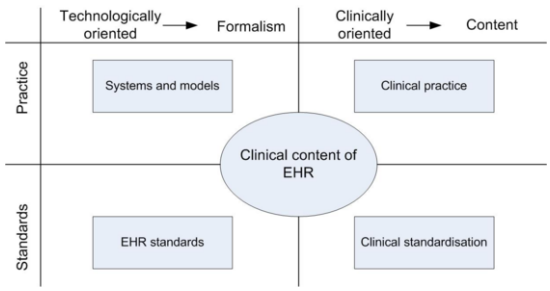

Figure 5- Factors contributing to the complexity of modelling clinical content of EHR systems.

The need for integration of the clinical and technical fields, as described in the above example, is a challenge that has also been identified in the international literature. In some studies, the focus has been on sharing experiences of how to manage EHR systems so that they support clinical practice. In [10], the modelling is done by a proprietary and simple XML-based model, without following a specific standard. This means that, in order to make the model clinically useful, technical standardisation is under-prioritised. In other studies, focus is on using an international EHR standard to model a clinical setting. In [2], openEHR archetypes were modeled, but they were not considered comprehensive and general enough to represent the maximum dataset because they were tailored to local needs. Since maximum datasets are a prerequisite for something to be considered an openEHR archetype, the newly modeled archetypes could not be fed back to the openEHR organisation directly. This means that experience regarding clinical aspects may be lost or delayed because the selected standard is not completely followed.

The method that we have introduced, inspired by Hevner et al., could be a tool to bridge standardisation and user needs in contrast to the above examples, where either technical standardisation or clinical usefulness is chosen. However, the method needs to be evaluated more thoroughly and to include more empirical work in order to ensure cooperation between relevant regional and national organisations. These organisations would include not only regional EHR projects and national eHealth bodies, but also clinical personnel, medical societies, EHR standardisation organisations and vendors of EHR systems so as to reflect the complexity of balancing regional and national approaches and achieving interoperability.

Conclusion

Coordination of regional EHR projects and national or international standardisation approaches is a prerequisite for achieving semantic interoperability. In this study, a method is proposed that makes standardisation manageable in a regional context. However, the complexity of balancing regional and national approaches and achieving interoperability should not be underestimated. Cooperation is needed between regional EHR projects, national eHealth bodies, clinical personnel, medical societies, EHR standardisation organisations and vendors of EHR systems in order to fully accomplish the task. Future work will include studying the feasibility of a clinical content format, by implementing a tool to develop and share clinical content in a specific Danish region and systematically acquire results in a longer time span.

Acknowledgements

We would like to thank the clinical content organisations in the Capital Region and Odense University Hospital for interview. Connected Digital Health in Denmark has also been most helpful in completing the study.

Abstract

Practicing physicians have limited time for consulting medical knowledge and records. We have previously shown that using icons instead of text to present drug monographs may allow contraindications and adverse effects to be identified more rapidly and more accurately. These findings were based on the use of an iconic language designed for drug knowledge, providing icons for many medical concepts, including diseases, antecedents, drug classes and tests. In this paper, we describe a new project aimed at extending this iconic language, and exploring the possible applications of these icons in medicine. Based on evaluators' comments, focus groups of physicians and opinions of academic, industrial and associative partners, we propose iconic applications related to patient records, for example summarizing patient conditions, searching for specific clinical documents and helping to code structured data. Other applications involve the presentation of clinical practice guidelines and improving the interface of medical search engines. These new applications could use the same iconic language that was designed for drug knowledge, with a few additional items that respect the logic of the language.

Keywords:

Iconic languages, Nonverbal communication, Computerized medical records systems, Practice guideline, Documentation.

Introduction

During consultations, physicians frequently need to refer to medical knowledge; however they have very little time to do so, and the amount of knowledge available to them is becoming increasingly vast. It has been shown that, when trying to find the answer to a clinical question, physicians give up after a short time, usually less than two minutes [1]. A possible solution to this problem is to display medical texts in a graphical form. We previously [2, 3] developed VCM (*Visualisation des Connaissances Médicales*, medical knowledge visualization), an iconic language for drug monographs, and we have shown that these icons can help physicians to search for contraindications, cautions for use or adverse effects.

Although initially developed for drug knowledge, the VCM iconic language contains icons that represent most general medical concepts, including diseases, antecedents, risk factors, drug classes, tests and procedures. VCM could thus potentially be used in many other applications outside the initial scope. Drug monographs only represent a small part of the vast amount of medical information and knowledge required by physicians during consultations. Medical knowledge also includes clinical practice guidelines that provide recommendations related to specific diseases. Patient records present physicians with certain challenges, whether looking for specific information or to obtain an overview of the patient. Physicians also need to use search engines efficiently to navigate and search the large number of existing medical documents.

These considerations prompted us to start the L3IM (*Langages Iconiques et Interfaces Interactives pour la Médecine*, iconic language and interactive interface for medicine) project [4], financed by the French National Research Agency in the program TecSan (ICT in Health). This project aims to explore the potential use of VCM for other medical applications, and to identify the icons that are lacking in VCM but that are needed for an iconic language that covers the whole medical domain. The objective of this paper is to investigate the potential of iconic approaches for patient records, clinical practice guidelines and medical search engines.

We firstly briefly describe the VCM iconic language and its use for drug monographs. We then describe the methods used for identifying new areas of potential application of VCM. In the results section, we describe these applications and the new icons that will be required in addition to the existing icons in VCM. Before concluding, we discuss the limitations of our

study and the advantages and disadvantages of using iconic languages.

Background: the VCM iconic language and "Mister VCM"

Drug monographs are texts describing drug properties, such as contraindications and adverse effects. Our previous work involved the creation of VCM [2], an iconic language for drug monographs, including a set of graphical primitives (about 100 pictograms, shapes and colors), and a few rules for combining the primitives to create icons for the major patient states, diseases, antecedents, risk factors, drug classes and follow-up procedures (Figure 1). For instance, the heart, kidney or lung pictograms can be combined with insufficiency, pain or bacterial infection shape to create icons for heart failure, renal failure, pulmonary infection,... and colors are used for distinguishing past, current and potential future diseases. The design of the iconic language took into account findings from cognitive sciences studies, in particular for the graphical representation of *is-a* relations. Consequently, when a physician visually searches for icons meaning "cardiac diseases", he will also find icons meaning "angor" or "cardiac failure".

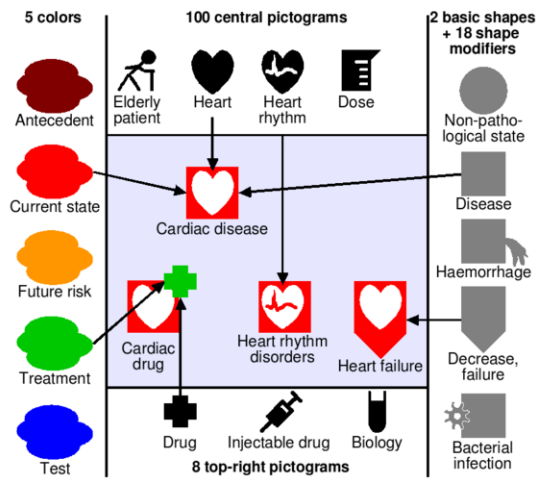

Figure 1 - Examples of VCM icons, created by combining pictograms, shapes and colors

Drug monographs are far too precise for the entire text to be replaced by icons. These texts also serve as legal references. However, icons may still facilitate the comprehension of the text, help to find a specific information, and provide an easy-to-memorize summary. Thus, we designed "Mister VCM" (Figure 2), an iconic interface for conveying information on the drug properties described in drug monograph to a physician during consultation [3]. VCM icons were used to represent contra-indications, cautions for use or adverse effects of a drug. These icons were displayed in a schematic diagram, based on anatomy and etiology. Rules were defined for combining icons when several of them apply to the same case on the diagram, using icons' *is-a* relations. When the physician clicks on an icon, the corresponding textual paragraph from the drug monograph is displayed. "Mister VCM" uses grey icons to indicate the absence of contraindication or caution for use related to a given anatomical system or etiology. This allows the physician to quickly view, for example, that a drug has no renal contraindication, whereas in the drug monograph text, he must read the entire contraindication section.

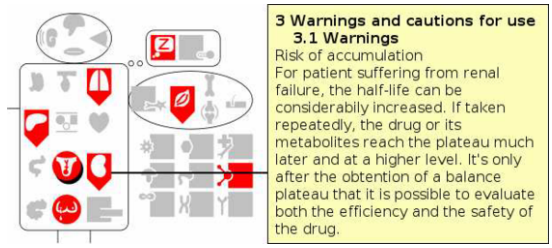

Figure 2 - "Mister VCM" displaying the contraindications of zolpidem, after the clicking on the renal failure icon

Evaluation in a controlled environment showed that with "Mister VCM", physicians briefly trained in VCM identified drug properties twice as quickly as when using a textual interface, and made significantly fewer errors [3]. The physicians were enthusiastic about using VCM, asking for such icons in their software.

Materials and Methods

The various potential applications of VCM that may be of use to physicians were identified through several steps. The use of "Mister VCM" to obtain information about drugs knowledge was firstly evaluated and followed by a focus group; during the discussion, the participating physicians suggested a few uses for, such as the use of "Mister VCM" for displaying information contained in patient records. We then carried out some preliminary investigation, involving master students. This led us to set up the L3IM project [4], involving eight academic, industrial and associative partners. The project design process also entailed some individual reflection.

During the first six months of the project, several focus groups containing GPs or hospital physicians were set up (for a total of 20 physicians). An initial set of focus groups, formed before presenting VCM to the physicians, was aimed at determining the problems they encountered in the use of the existent medical software. A second set was formed after the physicians learned VCM. These groups were dedicated to determining possible applications for VCM. All discussions during the focus group meetings were recorded and analyzed.

Results

Possible applications for VCM

At least three areas for the applications of VCM were identified: patient records, clinical guidelines and search engines.

The use of VCM for patient records

During consultation, physicians often have difficulties obtaining a clear overview of a patient's state, or finding a specific document relating to the patient, such as a hospital discharge summary. This is particularly true for patients with a long history of chronic diseases, or who are not regularly seen, for example for a patient followed by a doctor replacing a colleague on holidays.

Patient records contain patients' information including antecedents, current diseases and treatments, risk factors, biological test results... Patient records also contain clinical documents, such as radiographies, post-operative reports or discharge summaries, particularly for patients in hospital. We identified three possible uses of VCM to help the interpretation of patient records.

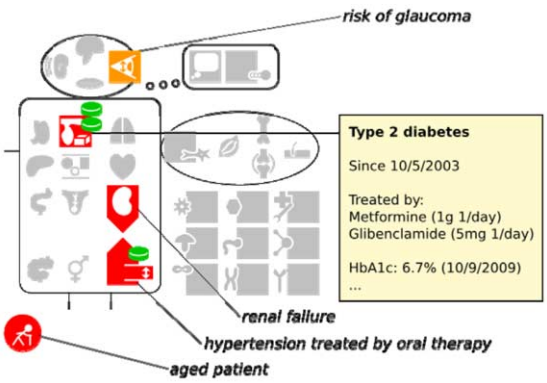

Figure 3 - Example of the use of "Mister VCM" for presenting a summary of a patient's conditions. Labels have been added to explain the meaning of the VCM icons.

- Icons can be used to summarize and to give a quick overview of the patient's conditions, possibly using a "Mister VCM"-like diagram. Figure 3 shows an example for an elderly diabetic patient, with hypertension and renal complications, and a risk of glaucoma. It displays a summary of the patient's current clinical conditions (diabetes, renal failure, hypertension) and risks (glaucoma), organized as a function of anatomy and etiology on a schematic human silhouette. Additional patient characteristics, such as age classes, are indicated below the silhouette. The icons also provide some information about treatments (*e.g.* oral bitherapy for diabetes). This iconic summary could be useful when reading medical knowledge such as contraindications, and may help to prevent an element being forgotten in the follow-up of the patient. Additionally, further information, such as related biological test results or prescription details, could be displayed by clicking on the icons.
- Icons can help physicians to search the various documents attached to a given patient. Documents could be placed within "Mister VCM" as a function of the various hospital services they come from, which are usually associated to an anatomical system or a particular etiology, *e.g.* cardiology or infectiology. Documents can also be characterized by other attributes, such as the type of the document (for example discharge summaries) or the author; this information could be added to the icons.
- Icons could help physicians to add structured data into patient records, for example the ICD10 (International Classification of Disease) code I10 instead of simply writing "hypertension" in plain text. Terminology browsers used for coding patient antecedents could be enhanced by adding icons in addition to, or in place of, the term's textual labels. Given that many terminologies are based on anatomy and etiology, "Mister VCM" could also be used to display the first level of the terminology, *e.g.* ICD10 chapters. Terms could also be searched for by composing the corresponding VCM icon, *i.e.* combining a color, a shape and a pictogram.

Applications in clinical practice guidelines

As for drug monographs, clinical practice guidelines are long texts that are difficult for the physician to read during a consultation. They often include many paragraphs applying only to certain patients, such as the elderly or patients with renal failure. Two applications were considered:

- Icons can be used by the physician to find the paragraphs that apply to the patient. This can be achieved by adding icons in the margin of the text, the icons indicating the various categories of patients addressed (Figure 4). Icons could also indicate the associated recommendations such as recommended prescriptions. Another possible application is the use of "Mister VCM" to summarize the various conditions, displaying the relevant paragraphs on demand.
- Icons can also be used to summarize the decision process recommended by the guideline, possibly using a decision-tree structure. Such a diagram could indicate the disease covered by the guideline, the various patient conditions and the associated recommended treatments or tests to be performed. The diagram could be used as a quick summary of the guideline, but also as an interactive table of contents, *i.e.* by clicking on the icons the physician could navigate through the text of the guideline.

Applications in search engines

Several search engines are dedicated to medical documents, such as Pubmeb for research articles or CISMeF [5] for French medical documents, including guidelines and medical

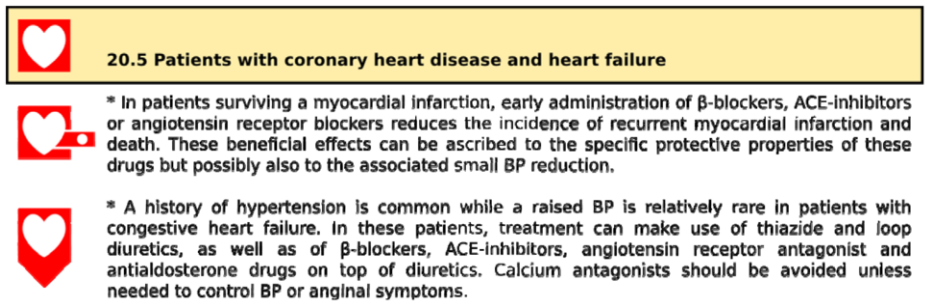

Figure 4 - An excerpt from the European Hypertension Guidelines 2007, tagged with icons inspired from the VCM iconic language. Icons tag the patient conditions addressed by the paragraphs.

courses. However, searching for medical documents is not easy, because the request can be complex and difficult to phrase. Additionally, the list of documents returned by the engine can be long, making it difficult to find the relevant documents, especially if the documents themselves are long, involving several topics like epidemiology, diagnosis, therapy... as it is often the case for guidelines.

Two different applications of VCM icons to facilitate the use of search engines were considered:

- Iconic interfaces could be used to help to formulate a query in a search engine, possibly using a "Mister-VCM"-like interface for choosing the icons on an anatomical and etiological basis. The use of icons eliminates language-related problems, such as synonymy, for example by using the same icon for angor and angina pectoris. However, since icons are not as precise as text, text may be required to refine the query.
- Icons can improve the list of documents resulting from the search. Documents in the list can be tagged by icons, according to their corresponding keywords. The use of a "Mister-VCM"-like diagram for this purpose would not be practical, as each document may involve many anatomic locations and etiologies.

In search engines, resources are indexed with various terminologies, for example MeSH (Medical Subject Headings) terms for CISMeF. Therefore, if these terminologies are mapped to VCM icons, icons could be easily associated with each resource.

Additional icons required for the new applications

In the previous section, we have described several new applications for the VCM iconic language. Given that VCM was initially developed for drug knowledge, some of these applications would require the language to be complemented with new icons, representing additional medical concepts. We have identified the following possible new icons:

- Icons for the different categories of health professionals. These icons could be used to identify the authors of documents attached to patient records. Existing anatomical pictograms could be reused to design icons that represent many different specialists, *e.g.* heart for cardiologists. Other health professionals, such as GPs, pharmacists, nurses,..., would require new pictograms, as well as would some other specialists, such as radiologists.
- Icons for representing document types. Two categories can be considered: documents attached to patient records, such as medical imaging document, post-operative reports or discharge summaries, and documents indexed in a search engine, including clinical guidelines, medical courses and patient leaflets. Within the second category of documents, it would be of interest to distinguish guidelines supported by national or local authorities, from foreign guidelines.
- Icons for representing social aspects of the patient, for example whether the patient lives alone or has low health literacy. These icons would be helpful in patient records, but could also be used in some clinical practice guidelines.
- Icons for diseases need to be extended, to incorporate additional elements representing the severity of the disease, or its evolution: aggravation, stabilization, improvement,... These icons could be used in clinical guidelines, since the recommendations given in guidelines are frequently dependent on the progression of the disease.

These new icons can be added to the VCM iconic language without modifying the existing icons and combinatory rules.

Discussion

In the results section, we have described seven applications for the VCM language, relating to patient records, guidelines and search engines. These new applications would use the already existent VCM icons for patient conditions, drug treatments,... and eventually new icons requiring a few additional elements to be incorporated into the VCM language. These elements must be added taking care that the language remains coherent. We considered new icons for distinguishing between different pharmaceutical classes, such as beta-blocking agents or angio-

tensin converting enzyme inhibitors for antihypertensive drugs, which may be useful for clinical practice guidelines. However, these new icons were not retained due to the limited empty space available on VCM drug class icons, and because pharmaceutical targets are difficult to represent by pictograms without adding textual abbreviations such as "ACE". The implementation of the new applications we described would be facilitated by mapping VCM icons to standard medical terminologies, which is an undergoing work.

These new applications for VCM need to be properly evaluated, possibly using a method similar to the one used to evaluate VCM application for drug knowledge. It would also be interesting to evaluate the successive use of VCM in various applications, such as in the following scenario: a physician searches for a guidelines document using a VCM-powered search engine, then views a VCM-annotated copy of this document, at the same time looking for information in a patient records featuring a "Mister VCM" summary. In particular, it would be important to determine whether the successive use of the same iconic language has a synergetic effect, or whether it is likely to cause confusion.

The use of icons has two main advantages over text (including short abbreviations, *e.g.* HbA1c for glycosylated haemoglobin): icons can be visually searched very quickly, and they are (at least partly) independent of native languages. However, icons may not be easily visualized for certain individuals, such as people with daltonism. Another inconvenient is that iconic languages such as VCM require a short training phase before being able to understand all icons of the language. For VCM, the learning phase is short, and was estimated to about four hours [2].

A few other uses of icons for presenting medical knowledge can be found in the literature, mostly for giving instructions to patients [6- 9], but also for helping medical students to understand physiopathology [10] or for summarizing the solubility and stability of injectable drugs for hospital pharmacists and nurses [11]. However, these icons are limited to the specific application they were designed for, and most of them are simple sets of pre-defined icons without compositional rules for creating new icons.

The new applications that we identified for VCM were focused on use by physician. Other applications could be identified for other groups of individuals, in particular medical students, pharmacists and nurses. However, VCM is probably not appropriate for patients. Indeed, the VCM language was designed taking into account the medical knowledge acquired by health professionals, especially anatomy, whereas patients have only limited knowledge in this domain [12].

In conclusion, iconic languages have many possible applications in medicine. In order to avoid health professionals having to learn several icon systems, and to prevent the potential confusion between icons developed for different applications, a single, coherent and standardized iconic language should be used across the various applications. In this paper, we have shown that, with the addition of a few new icons, VCM could be this iconic language.

Building a Logical EHR architecture based on ISO 13606 standard and Semantic Web Technologies

Marcelo R. Santos[a], Marcello P. Bax[a], Dipak Kalra[b]

[a] *Information Sciences School, Minas Gerais Federal University, Belo Horizonte, Brazil*
[b] *CHIME, University College London, United Kingdom*

Abstract

Among the existing patterns of EHR interoperability, the ISO 13606 standard is an important consideration. It is believed that the use of this norm, in conjunction with semantic technologies, may aid in the construction of a robust architecture, keeping in mind the challenges of semantic interoperability. The objective of this paper is to present a proposal for an EHR architecture, based on ISO 13606 and on the utilization of semantic technologies, for a real EHR scenario. In order to accomplish that, a real EHR scenario is described, as well as its main interoperability requirements and a candidate architecture is proposed to solve the presented challenges of interoperability. The ability of the ISO 13606 EHR reference model to accommodate the scenario was highlighted, together with the support provided by the use of the ontology specification languages – RDF and OWL – in respect to the maintenance of a controlled vocabulary.

Keywords:

Electronic Health Records, Semantic Interoperability, ISO 13606 standard, Two-level Modelling, Archetypes, EHR Service Architecture

Introduction

The issue of interoperability between EHR systems has become, in recent years, a theme of great relevance for the international clinical and informatics communities. The realization that the construction of an integrated EHR system will always involve, at some level, interoperation between different systems, underlines the relevance of interoperability patterns and of semantic technologies in the current context.

In order to understand this assertion, let us consider the creation of an integrated EHR service for a city, state or country. Although it is possible to develop a single EHR system, which fulfills the needs of every health institution in a city, this system will need to be integrated with those of other cities, which will then form the EHR service at the state or regional level. Likewise, it is possible to have a single EHR system for a given state, that will in turn be integrated to those of other states, in order to obtain as EHR service for the country. The same reasoning applies in the case of the obtainment of an EHR service in a global scale.

In this paper the name Logical EHR is given to this arrangement of different EHR systems capable of interoperating so as to offer an integrated service, preserving the existing semantics in the knowledge domain, updating clinical data for every patient in a consistent way, rather than ambiguously, all in accordance with the legal ethical regulations and obligations, following the safety and confidentiality patterns of information. The basic premises for the creation of a Logical EHR are the existence of interoperability patterns and the utilization of semantic technologies.

An example interoperability pattern, which may enable the creation of a logical EHR, is the ISO 13606 standard. It is an international standard published by ISO that specifies the information models and vocabularies needed for the interoperability of EHR systems. Initially developed by the European Committee for Standardization (CEN), with the denomination EN 13606 (*Electronic Health Record Communication*), and is a subset of the architecture proposed by the *openEHR*[1] Foundation [8][9][5]. In summary, it proposes a model of EHR statements that represents the complete or partial information of a patient's health record, extracted from an EHR system, for the purpose of communication to another EHR system or other requesting system.

Concerning semantic technologies, one might observe that, although the Internet offers sufficient flexibility and space in terms of connectivity for reaching interoperability, the techniques traditionally used for integration and interoperability at the application level involve only the use of data exchange formats whose success in terms of semantic has not been very significant. However, the use of semantic technologies in order to facilitate the integration and interoperability of EHR systems may bring significant benefits [4].

[1] The *openEHR* approach is a comprehensive open specifications for EHR systems originally based on the results of the European Union's GEHR-Project in the early 1990s http://www.openehr.org

This paper aims at presenting a proposal for an EHR architecture, based on the ISO 13606 standard and on the utilization of semantic technologies, for a real EHR scenario.

ISO 13606 standard

The ISO 13606 standard was developed by the Technical Committee ISO/TC 215, Health Informatics, and conceived from practical experience obtained during the implementation of the European precursor pre-standard, ENV 13606. It is a subset of the reference model proposed by *openEHR*. Based on the two-level modeling approach, it defines an information architecture to communicate part or the entire electronic health record of a given patient: preserving the original clinical meaning intended by the author; and reflecting the confidentiality of each data as intended by both author and patient [8].

The *two-level modelling* approach is based on the separation of knowledge and information levels in information systems [1][2]. The Information level represented by the reference model that are statements which apply to all entities of a class [1].The Knowledge level is represented by clinical archetypes that are statements about specific entities.

The reference model represents the global characteristics of components of an EHR, how they are assembled, and the information context required to meet the ethical, legal and originality requirements. It defines the following containers: *EHR_Extract* – the electronic health Record for one person; *Folder* – high-level organization of the EHR; *Composition* – Clinical care session, encounter or document; *Section* – clinical headings reflecting the workflow and consultation process; *Entry* – Clinical "statements" about observations, evaluations, etc; *Cluster* – Nested multi-part data structures; *Element* – Leaf nodes with single data values.

This reference model is complemented by clinical data structure definitions, known as archetypes, which represent the clinical concepts agreed upon within a community, with the objective of guaranteeing interoperability, consistency and data quality. An archetype is a formal definition of prescribed combinations of basic classes in the reference model for a specific clinical domain or for organizations, expressed in the form of data restriction. In the ISO 13606 standard they are defined in Part 2, supported by Part 1 but not mandatory [7].

The following may be quoted as benefits of the use of archetypes [6].

- Enable the formal definition of clinical content by domain experts without the need for technical understanding;
- Preserve the meaning of data by explicitly specified and well structured clinical content;
- Can safely evolve and thus deal with ever-changing health knowledge using a two-level approach;
- Can simplify the use of clinical terminologies.

Definitively the ISO 13606 contributes to the Logical EHR approach, as we can see at the Figure 1.

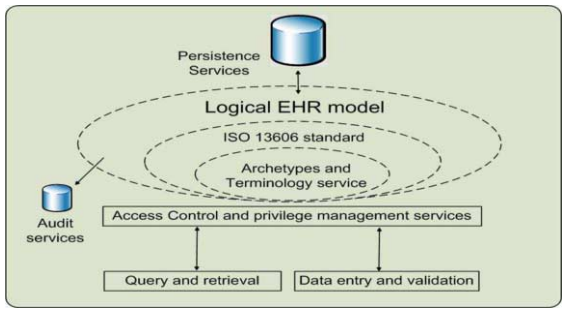

Figure 1 – Logical EHR architectural components

Semantic Technologies

"The Semantic Web is an extension of the current web in which information is given well-defined meaning, better enabling computers and people to work in cooperation"[12].

The initiatives in the field of Semantic Web establish a set of protocols and technologies which promise to improve data categorization and association through an increase in the ability to create relationships and to generate inferences between systems and data. Adding intelligence to the traditional services offered by the web – based on Service Oriented Architecture (SOA) – and make stored data accessible by a set of semantic technologies [13].

In a typical interoperability scenario based on the SOA architecture, systems interact via Web Services using XML and SOAP messages on top of an HTTP network protocol [11]. The challenge of this architecture is to enable heterogeneous web applications, written in different platforms, to be integrated, exchanging data in a user-transparent way. This approach handles messages in an efficient way, but it does not consider the compatibility of the vocabulary being used and does not guarantee that the message recipient is able to comprehend its content [13]. This difficulty has led to W3C's[2] efforts to incorporate semantic technologies as part of its Semantic Web Services initiative.

Two W3C specifications are highlighted on the Semantic Technologies: Resource Description Framework (RDF) and Ontology Web Language (OWL). The RDF provides a framework to establish relationships among data elements, and the OWL improves the RDF with an ability to make constraints on different data elements and their relations with others. RDF and OWL can operate together depending on the scenario. Another important W3C specification is the Web Ontology Language Service specification (OWL-S) that provides a flexible framework for describing and initiating web services [13].

Materials and Methods

This study was carried out at the Department of Health for the State of Minas Gerais (SES-MG[3]), specifically within the scope of the electronic records of the Family Health Program. The Project was begun in the last quarter of 2008 and the main development phase to continue to 2011. Based on the results of grade tests which took place previously [10], the ISO 13606 standard was used as a starting point for the construction of the EHR statements and modeling of the archetypes for the central repository. The proposed architecture was developed from the direct participation of the author in the technical team of SES-MG and PRODEMGE and it was officially accepted in August 2009.

Firstly, the analysis of requirements for interoperability for the EHR project was performed. These were identified by means of brainstorm meetings and specific interviews involving the clinical team at the SES-MG – composed of ten members – at least fifteen technical visits to the health units in the state and research of previous projects and inside documents. These activities were undertaken in the initial 6 months of the project. At the same time, three members of the clinical team ran workshops with the clinical area participants of SES-MG in order to identify the data elements that should be part of the Patient Clinical Summary. After the architecture's approval, the archetype modeling process commenced. The archetypes were developed with the help of editor *linkEHR*[4] and the terminologies to be part of the terminology service were identified while modeling each of the archetypes.

Through an analysis of interoperability requirements and research on the utilization of semantic technologies for the creation of a terminology service, it was possible to elaborate the candidate architecture presented here.

Electronic Health Record Scenario

The Department of Health for the State of Minas Gerais, interested in the benefits brought about by the use of integrated clinical information, intends to create a state-wide EHR repository, with the objective of consolidating each citizen's demographic data and clinical summary. Initially the scope of the project will include only primary care centers in the Family Health Program. However, the objective of the government is to create the foundation for the inclusion of secondary and tertiary care units in the EHR repository.

The State of Minas Gerais is the largest in the country in number of cities, totaling, according to the Brazilian Institute of Geography and Statistics (IBGE[5]), 853 cities. For delivering primary care services, the State has over 5000 health units distributed among its cities, according to information from the SES-MG. The government's proposal is not to develop a single EHR system for the State to be imposed on the cities, conversely, it is to create macroregions and deploy EHR system contracted from the market to service each one. The solution is based on the creation of a central repository and on the creation of a message infra-structure aiming at the interoperability of the EHR systems to be contracted. The repository shall contain the demographic data and a clinical summary of the patients, necessary to support to the Family Health Program.

Each of the afore mentioned macroregions, composed of several health units, will use its own choice of EHR system and will have its own datacenter. The architecture must clearly establish the rules of data exchange so that the solutions access and provide data updates to the central repository, as well as prioritize the utilization of a controlled vocabulary.

Interoperability requirements

As a result from the data survey done with members of the SES-MG, a series of interoperability requirements were identified. A summary of the key requirements is outlined below.

A set of general requirements:

- The central repository should centralize the demographic data and each patient's clinical summary ;
- The EHR systems should feed the central repository and not interoperate directly with each other – EHR system integration should always occur via the central repository;
- Every time clinical data is recorded in the EHR system, the central repository should be updated;
- Before a patient is entered in the EHR system, the central repository should be checked. If the citizen already exists in the central repository, the centrally-held data should be copied to the requesting EHR system.

A set of specific requirements for the central repository:

- It should allow for the structuring of its data elements through a standardised reference model and archetypes;
- It should provide a mechanism which enables the recording and retrieval of each patient's clinical information;
- It should provide a mechanism which enables the recording and retrieval of each patient's demographic information;
- It should provide the EHR system with an authentication mechanism for the identification of the system and its operators;
- It should provide a repository of terminology services, which would serve as basis for the creation of the common vocabulary for the exchange of information with the EHR systems;
- It should provide auditing and reporting services.

[3] Department of Health for the State of Minas Gerais http://www.saude.mg.gov.br

[4] LinkEHR was developed by the Biomedical Informatics Group at the Technical University of Valencia, Spain. http://www.linkEHR.com

[5] Brazilian Institute of Geography and Statistics http://www.ibge.gov.br

Set of requirements for each EHR system:

- It should implement mechanisms for clinical and demographic data exchange with the central repository;
- It should implement mechanisms for the authentication and data security to ensure the data communication with the central repository;
- It should be able to exchange data with the central repository according to the terminology predicted by the terminology service;
- It should be able to exchange data with the central repository, respecting the restrictions defined by the archetypes, which represent the data elements from the central repository;
- It should be able to supply information for audits of any nature.

These requirements served as the basis for the design of the central repository and established key elements for the construction of the service architecture presented below.

EHR Services Architecture

The proposed architecture uses archetypes for the representation of its data elements and was designed with four basic services: clinical data services, demographic data services, archetype services and terminology services. See Figure 2.

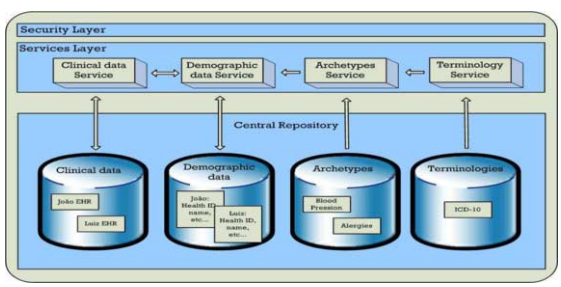

Figure 2 – EHR Services Architecture

Demographic data services are divided into: Demographic data inclusion service, alteration of demographic data service, user deactivation service, service of user consultation by code and service of user consultation with parameters. The Brazilian government has a published standard for sending and receiving data from the national health card. It was decided to utilize this standard, which is based on the utilization of Web Services, for exchanging messages in XML language.

The clinical data services were designed considering the utilization of EHR statements constructed from the reference model of the ISO 13606 standard and *datatypes* specified by the CEN/TS 14796 [3]. Two services were proposed: one for sending data to the central repository and another for enabling the retrieval of data from the central repository.

For sending data to the central repository, the EHR systems will have daily to generate the clinical statements (within *Compositions)* which took place for each patient at the health units, and update the central repository overnight. For that, they will have to consult the archetype structure through the archetype service available, and research the *Sections, Entries* and *Cluster/Elements* that will make up each *Composition.* For the update of the central repository, the statements shall be compacted according to a compacting algorithm yet to be established, and sent via FTP protocol. Since the architecture specifies the utilization of a repository with EHR version control, every time there is a correction or deletion in the clinical data, the EHR system shall send an update statement with the altered data, according to standard established by the ISO 13606 standard.

With regard to the retrieval of clinical data, this will only occur whenever a patient moves from one macroregion to another, or when the EHR system needs, for whatever reason, to update its local database. For that, the EHR system shall send a request to the central repository, and receive an XML file online with the current version of the Patient Clinical Summary (within a *Composition*). For this reason the architecture includes the design of two clinical databases: Patient Clinical Summary database and Clinical History database. The archetypes will include the rules to keep the each data element up to date at the Patient Clinical Summary database. Keeping these databases it will be possible also retrieve all *Compositions* of a Patient from the Clinical History database if it is required. In both cases, because of the version control process, only the most recent version of each object will be considered (if there have been corrections made to an original version).

The terminology service was designed to make it possible that all of the vocabulary content to be used by the EHR systems for integration with the central repository is made available through a unified source. Terminology such as ICD-10, procedure tables, medications, laboratory exams and terminology internal to the SES/MG will be available. The idea is to facilitate access to the terminology by the EHR system, promoting the development of the Logical EHR environment expected by the State. Furthermore, whenever the central repository receives EHR statements from the EHR software, there will be the need to perform syntax and semantic validations on the statement. Within this context, the use of semantic technologies, through the encoding of terminology in ontology representation languages such as RDF(s) and OWL will be a point of great relevance for the project. All terminology will be made available through the same service.

The archetype service was designed to make it possible for contracted EHR systems to request the versions of published archetypes. This is a critical point, for it will enable the gradual publication of new versions of archetypes, facilitating the deployment of the central repository in its initial phase. It will also facilitate the implementation of concepts which will be used later for other health care settings such as public hospitals.

Discussion

The utilization of a unified terminology server, based on the use of semantic technology, in conjunction with the single reference model published by the ISO 13606 standard will enable the establishment of a Logical EHR for the State. But that the work undertaken to date has shown that the architecture alone would not be sufficient to guarantee that the semantics present in the knowledge domain be, in fact, homogeneous. There will be the need for introduction of descriptive terminologies (e.g. SNOMED[6]) and monitoring on the part of the State's clinical team, in terms of audits focusing on the quality of information recorded in the central repository.

Despite the fact that the central repository is based on a reference model and on archetypes - which will allow for a robust and yet adaptable setting for the establishment of a Logical EHR environment and greater flexibility for the introduction of new concepts in the repository - the architecture needs to anticipate the participation of EHR systems that do not use the archetype approach. The EHR system need to, at least, be able to:

- identify the restrictions to which each data element must be submitted, through formal representation in ADL;
- create and interpret messages in XML according to the pattern presented by ISO 13606;
- validate the data elements to be sent to the central repository using the terminology service, by means of RDF and OWL schemes.

It is believed that the frequency of publication of new archetype versions by the SES-MG might be able to sparkle the interest of software suppliers in automatically interpreting the formal specifications predicted in the archetypes. This way, they might be able to obtain a cost reduction in the process of updating new clinical concepts and the terminology adoption in their EHR system.

Conclusion

This paper has made evident the importance of the Logical EHR concept, since the scenario of EHR systems utilization normally involves the integration between different software applications. It was possible to observe the adjustment of the two-level modeling approach, which was the basis for the construction of the proposed architecture, regarding the level of information represented by the reference model, as well as the level of knowledge represented by the archetypes. These allowed for the mapping of all the data elements that constitute the central repository and provided a greater flexibility to the proposed architecture. From the terminologies point of view, the semantics technologies propitiated a favorable setting for the use of a controlled vocabulary, increasing the chances of preserving the semantics of the knowledge domain. It was verified that the reference model for the ISO 13606 standard was appropriate for fulfilling the requirements of interoperability of the case researched, and its statement (*Entry*) model was enough to fulfill the EHR specificities of a Brazilian State. Furthermore, it allowed the participation of EHR systems that do not use the archetype approach.

Case Study: Analysis of End-User Requests on Electronic Medical Record and Computerized Physician Order Entry System of Seoul National University Hospital in Korea

Young-Ah Kim, Soo-Yong Shin, Eun-Mi Jo, Chan-Hee Park, Min-A Hwang, Kyung Hwan Kim, Chun Kee Chung

Medical Information Center, Seoul National University Hospital, Seoul, South Korea

Abstract

Seoul National University Hospital (SNUH) in Korea has utilized the full Electronic Medical Record (EMR) system since October 2004. Unlike other countries, most EMR systems in Korean teaching and general hospitals are in-house development systems. Therefore, we can actively respond to user requests on EMR. Here, based on 5 years of experience in EMR system operation, we analyzed 2,339 SNUH EMR user requests from 2006 to 2008 for improvement of EMR system operation and management. We classify user requests into 9 criteria based on guidelines from the SNUH medical information management team. In conclusion, the most common requests (73 %) are for improvement of improving quality of care. However, requests associated with hospital enterprise, public policy, and customer service are gradually increased every year. Therefore, we suggest that suitable EMR management criteria are necessary for reliable EMR operation and management.

Keywords:

Computerized patient record, Computerized physician order entry, Management information systems

Introduction

Seoul National University Hospital (SNUH) is the first modern hospital in Korea since 1885. It now has 1,754 beds, with 563,712 inpatients and 1,850,473 outpatients per year. As one of Korea's largest teaching and general hospitals, SNUH received the Korea Brand Power Index Award for 9 consecutive years [1] and was ranked first in the 2004 National Hospital Evaluation Program by the Korean Ministry for Health and Welfare. SNUH is also the first hospital in Korea to adopt an electronic medical record (EMR) system in all hospital units. The computerized physician order entry (CPOE) system was launched in 1999, and the EMR system in 2004. Representative goals of EMR and CPOE in SNUH include saving space and time, integrating management of medical information, improving quality of medical records, supporting diverse data formats, data recombination, clinical decision support, information exchange among medical persons or hospitals, and better communication. Consequently, SNUH is able to obtain significant outcomes using the EMR system [2], these include qualified medical products, prominent clinical research results, excellent medical evaluation rating, and good education guidance.

Active acceptance & application of end-user requests can result in achievement of these outcomes. 'End-user request' means requirements based on direct needs of medical and nursing users' on EMR. The requests can be actualized by EMR programming(including changing, improving, editing or supporting, etc.). Since most EMR and CPOE systems in Korea's teaching and general hospitals are in-house development systems, we can easily respond to user requests and implement them into the hospital information system (HIS). Besides the characteristics of system development, the reason that we actively collect end-user requests is to promote EMR ownership and participation. Adoption of the CPOE was relatively easy, due to its diverse and attractive merits. However, since SNUH has a long history of paper medical records, many hospital personnel were reluctant to use electronic medical records, in spite of the advantages of such as system.

In order to collect and reflect end-user requests, we set 'user-friendly' policy as a major HIS management policy at SNUH. 'User friendly' policy means that anyone who uses EMR or CPOE can meet his or her own requirements through diverse routes. In detail, there are three steps. The first step is to open diverse channels for acceptance of user requests, i.e. telephone call, bulletin boards, e-mail, and so on. This is important for encouraging active user participation. The second step is active and positive acceptance after discussion of requests through EMR system board members and end-users. At SNUH, the EMR system board member is composed of doctors, nurses, IT specialists, and programmers. The last step is suitable coordination. The EMR and CPOE systems are very complicated and are interconnected to each EMR program component. Therefore, the process of coordination with program developers and medical personnel is essential.

In this paper, we analyzed end-user requests for the three previous years for review in our study of 'user-friendly' policy. Based on 11 years of experience with the CPOE system and 5

years with the EMR system, we can propose a promising method for operation and implementation of a good quality HIS.

Materials and Methods

SNUH launched its CPOE system in October 1999 and its EMR system in October 2004. SNUH improved its CPOE and EMR systems with two major upgrades in 2005 and 2006.

We first collected SNUH end-user requests from 2006 to 2008, including requests for a second major upgrade in 2006 [3]. Unfortunately, no data on end-user requests was documented before 2006. The total number of requests for the previous three years was 2,339. We then classified the collected requests into 9 categories, which were defined by the SNUH medical information operation team on the authority of practical & political demands in SNUH. The categories are shown in Table 1. Detailed subcategories of each category are also shown in the table.

Table 1- Categories for EMR users' requests

Category	Sub-categories
Improving Quality of Care	Medical process optimization
	Newly established department
	Medical persons communication
	Program management
	Decision support
	Authority
	Device interface
Evaluation of Clinical Quality	Clinical quality index
	Hospital accreditation process
Service for Customer	Patient information privacy
	Patient safety
Government Regulation	National health insurance regulation change
	National health management policy change
Hospital Enterprise	Hospital process innovation
	Quality assurance
Statistics	Statistics of operation, admission, and discharge
Education	System for medical students
	Updating manuals
Clinical Research	EMR modification for clinical research supports
Miscellany	

Analysis Results

Table 2 summarizes user requests. The most frequent request category is "Improving Quality of Care," with a proportion of 73%. We can easily understand this result, since one of the most important purposes of using the EMR and CPOE systems is improvement of the quality of clinical care. The categories include "Evaluation of Clinical Quality" (12%), "Service for Customers" (5%), "Government Regulation" (4%), and "Hospital Enterprise" (1%). In 2007, the number of requests increased rapidly (from 540 to 913, 69.1%) due to nation-wide hospital accreditation in Korea, which is performed every three years. Therefore, the "Evaluation of Clinical Quality" category increased almost 1,000%. This rapid increase also confirms the importance of the EMR and CPOE systems in hospital management and operation.

Another interesting development is that as system end-users become accustomed to using the EMR system, they make more requests. The total number of requests in 2008 increased 64% compared to 2006. When we investigated user requests in detail, recent requests focus on more specific clinical purposes, rather than general bug fix requests. This means hospital personnel have begun to depend on the EMR or CPOE systems in their routine work.

Table 2- User requests on SNUH EMR

Category	2006	2007	2008	Total
Improving Quality of Care	466	572	674	1712
Evaluation of Clinical Quality	20	222	36	278
Service for Customer	24	27	72	123
Government Regulation	3	35	51	89
Hospital Enterprise	15	29	31	75
Statistics	2	10	9	21
Education	1	2	6	9
Clinical Research	1	6	0	7
Miscellany	8	10	7	25
Total	540	913	886	2339

As shown in Tables 2 and 3, the noticeable categories are "Government Regulation" and "Service for Customer." In government regulation, even though the number of requests is small, any request associated with this category is very complicated. For example, the Korean government pushed hospitals to integrate the real-time drug utilization review (DUR) system into their systems. The adaptation rate of electronic health records in US general hospital is very low [4]; however, the rate in Korea is relatively high [5] and has increased rapidly since 2004. Recently, most Korean general hospitals have

used EMR systems. In contrast to other countries, Korea has only one national health insurance agency, known as the National Health Insurance Corporation. Within this environment, the Korean government has begun to control hospital EMR or CPOE systems in order to promote public health.

Customer service is also important. As in Table 3, this category is almost 100% increased in its ratio (from 4.44% to 8.13%). This implies that EMR is an important tool for increasing the quality of patient service; SNUH is actively trying to utilize the EMR and CPOE systems in this category.

Table 3- Ratio of each EMR user requests category

Category	2006	2007	2008
Improving Quality of Care	86.30%	62.50%	76.07%
Evaluation of Clinical Quality	3.70%	24.32%	4.06%
Service for Customer	4.44%	2.96%	8.13%
Government Regulation	0.56%	3.83%	5.76%
Hospital Enterprise	2.78%	3.18%	3.50%
Statistics	0.37%	1.10%	1.02%
Education	0.19%	0.22%	0.68%
Clinical Research	0.19%	0.66%	0.00%
Miscellany	1.48%	1.10%	0.79%

Although the 'Improving quality of care' category has decreased in its proportion from 86.30% in 2006 to 76.07% in 2008, the number of requests has still increased from 466 in 2006 to 674 in 2008. This means that users have required much more diverse functionality from the EMR system by taking notice of its convenience and practicality, even though the EMR system is improved by reflection of every request.

A 2008 Survey of the HIMSS (Healthcare Information and Management Systems Society) shows results similar to those in Tables 2 and 3 [6]. Figure 8 of [6] shows "Improving Quality of Care," which increased from 56% in 2007 to 69% in 2008 and "Patient (Customer) Satisfaction," which increased from 36% to 55%. Our results show the same trends as mentioned above. Notice that results from the HIMSS survey of the "top business issues facing healthcare" are derived from CIOs or IT managers; however, our results are obtained from end-users. This implies that medical personnel, including doctors and nurses have begun to notice the importance of IT systems in healthcare.

However, there is a pitfall of 'user friendly' policy. Table 4 shows the number of medical user requests, accepted requests, requests implemented on EMR, and requests in progress. The "Accepted requests" category refers to requests approved by EMR board members; "implemented requests" refer to requests implemented on the EMR or CPOE system; "under development" refers to requests still under development after being accepted; and "withdrawal" represents requests that are withdrawn after being accepted.

Table 4- Summary of practically implemented user requests in the case of medical part

	2006	2007	2008
Total Requests(in medical part)	286	783	688
Accepted Requests	143	391	323
Implemented Requests	93	292	214
Under development Requests	48	98	109
Withdrawn Requests	2	29	42
Under development/ Accepted(%)	33.6	25	33.7
Withdrawn/ Total(%)	0.6	3.7	6.1

As in Table 4, the number of requests still in progress has increased. By trying to accept all possible user requests, users begin to rush very individual demands onto the EMR or CPOE system. In addition, users become accustomed to the system; therefore, requests become more complicated and interconnected to other programs. In some cases, users make contradictory requests, due to conflicting interests; or make requests that require a change in the business process. These problems cannot be solved by EMR board members, so increment of withdrawn ratio should be happened.

Since IT resources are limited, it is difficult to implement all accepted requests in time. As in Table 4, the ratio of underdeveloped requests is about 25~34%. This situation(slow implementation of user requests) causes user dissatisfaction. Therefore, IT managers should try to catch essential requests and prioritize them, furthermore, control programmers for building the accepted requests in time.

Discussion

Since implementation of the EMR system at SNUH as the first trial among major Korean teaching and general hospitals, there have been many concerns regarding adoption and implementation of EMR. Therefore, we have chosen a 'user-friendly' policy in order to improve user participation.

Fortunately, results of our analysis confirm that our 'user-friendly' policy is one of the key elements of success in adoption of the HIS system. End-users make more frequent requests as they get used to the system. The total number of requests in 2008 increased 64% compared to 2006; and users made 3.5 requests per business day in 2008. End-users have recently shown a desire to use the EMR and CPOE systems for improving customer service, as well as quality of clinical care. The board of hospital directors has begun to use the EMR and CPOE systems for management of hospital enterprises, including process innovation or simple financial statistics. Moreover, the government has noticed that HIS can be a useful tool for improving public health. In conclusion, EMR and CPOE system must be an essential tool for improvement of the quality of care.

However, 'user-friendly' policy brings other problems. For example, the complexity of the system has increased and the speed of the system has slowed down. Therefore, a balance must be established between 'user-friendly' policy and limited resources.

We must mention that the EMR and CPOE systems at SNUH are in-house development systems. SNUH also has an IT team that includes programmers. Therefore, we can actively collect end-user requests and implement the accepted ones on our HIS system. This can mean a significant difference between the SNUH system and those of other countries. It might be a key element for our successful EMR implementation.

Abstract

This study addresses the question of the respective impact of organizational vs. technical environment variables on the collaborative aspects of healthcare work situations. It analyzes the physicians-nurses communications during the medication use process, according to both the organization of their work and their technical environment. Participant observations, interviews and recording of the dialogs were performed in 4 hospitals functioning with either a CPOE or a Paper based system. The study (i) presents the identification and description of the communications' processes involving doctors-nurses face-to-face communications and the supports that mediate medication information and (ii) focuses on the amount of face-to-face communications depending on the organization of work and the technical system used. The analyses demonstrate that the organizational variables have a larger impact than the technical environment on the quality and quantity of the communications and cooperation activities.

Keywords:

Communication, Medical order entry system, Human activities, Work

Introduction

In many safety critical environments, technical automated systems prove efficient to reduce and prevent errors. In the healthcare domain, the medication use process has been extensively studied under the safety point of view and a huge amount of efforts has been made to support the implementation and adoption of Computerized Physician Order Entry (CPOE) systems to prevent medication errors [1]. Indeed, successfully implemented CPOEs prove efficient to achieve a significant reduction of Adverse Drug Events (ADE) [2]. However, sociotechnical or human factors qualitative studies repeatedly uncover unexpected and unintended negative effects of CPOE systems [3].

In the hospital setting, the work situations are inherently collaborative. The care of patients inevitably involves many different professionals, all needing to share patient information and discuss their management. The medication use process may be characterized as a complex distributed work situation: rather than existing in the mind of any particular individual, the cognition is distributed across the minds of the members of the clinical team and across physical media [4]. In this context, the critical role of doctors-nurses face-to-face communications has been largely demonstrated [5-6]. The professionals actually prefer direct communications for gathering information, more particularly about the medications which is the category of information most frequently sought by the professionals [7]. Moreover, the role of poor communication in generating avoidable error and poor outcomes is now widely discussed [8]. Since the responsibility of doctors and nurses are complementary rather than overlapping, a complete, coherent, and updated knowledge of the patient status requires a direct two-way information flow among team partners.

Some studies have focused on the impact of the implementation of CPOE applications on communications. Enthusiastic implementations of new technologies do not always have the consequences expected of them: most of the studies find that the technical system deteriorates the communication and cooperation activities [9]. This is in part because human communication processes are shaped into a form dictated by the technological system. There are essential differences between what happens in an informal conversation and what happens in a formal information system transaction [10]. But above all, there is a large number of factors that might influence communication behaviors, including the nature of available communication infrastructure, the nature of the work undertaken and the practices that are routinely applied within the organization. The technical environment might not be the most important determinant of the quality of professionals' communications. Doctor-Nurse cooperation and communications are also governed by the organization of their work.

The present study aims at highlighting the critical role of the organizational factors when implementing a CPOE application in the work situations. It analyzes the doctors-nurses communications during the medication prescribing-administration

process, according to both the organization of their work and their technical environment, CPOE vs. Paper. The study (i) presents the identification and description of the communications' processes involving doctors-nurses face-to-face communications and the supports that mediate medication information and (ii) focuses on the amount of face-to-face communications depending on the organization of work and the technical system used.

Context of the study

Sites of the Study

A paper-based situation study was undertaken in a 3000-bed capacity hospital referred to as H1, in three wards: Cardiology, Nephrology and Neurosurgery.

The CPOE situation study was undertaken in two different hospitals running the same IT system:

- a 550-bed hospital, H2 which had been running the CPOE for three years. The analyses were realized in two medical departments: cardiology / gastroenterology and infectious diseases,
- a 825-bed capacity academic hospital, H3 which had also installed the CPOE. The study took place in two pilot sites, the nephrology and immunology wards where the system had been in use for about 6 months.

Overview of the Medication Use Process in the European hospitals

According to national and local regulations, the tasks necessary to carry out the medication ordering and administration procedures are distributed across the physicians, the pharmacists and the nurses. All the physicians attend all the patients and so do the nurses and pharmacists. The physician is in charge of the therapeutic decision making and of ordering the meds. The nurse is not supposed to copy the physician's orders on any support except to validate the administration. She/he has to control the meds before administering them to the patient; she/he must validate the administration and eventually document any unexpected event. The pharmacist is in charge of controlling the prescription and of delivering the medications to the medical unit.

It must be noted that in the vast majority of European hospitals, unit-dose dispensing is limited to a small proportion of drugs. The products are globally dispensed in the wards (drugs for several patients and for several days), the nurses being in charge of storing them in the ward medications' locker. The nominative dispensing (drugs for a given patient for a given period of 24h to several days) has a particular organization with direct delivery of the medications to the nurses in the ward for the involved patient. These organizations of the dispensing necessitate a preparation phase from ward stock before the actual administration to patients. Nurses are in charge of this preparation.

We will describe in this paper some universal characteristics of the organisation for oral route meds and standard schedules.

Description of the two systems (paper-based and CPOE)

In the hospital setting, the therapeutic decision making and ordering tasks take mainly place during the medical rounds, where the physicians visit all the patients of the ward. With the paper-based system (H1), doctors perform the medical round using a wheel cart with the patients' medical files underneath. They write their medication orders on the medical orders' list which is structured with 3 columns dedicated respectively to the entry of the date of the order, its content, and the signature of the provider. Only new prescriptions or prescription changes are entered at each visit at the patient bedside. Nurses then organize the administration of oral routes medications. It is structured by the preparation of pill dispensers usually covering a 24 hours period. At some point in the 24 hours period (night shift, morning, evening), a nurse prepares the pill dispensers for all the patients of the ward. To perform it, the nurse can rely on the information contained in each patient's medication orders' list. She/he translates the prescription into suitable administration times and dosage forms according to their knowledge and the ward routines. During the 24h period covered by the pill dispensers, the physicians visit the patients and place new orders or modify the existing patients' treatments. These modifications require an update of the corresponding pill dispensers by the nurse. This update is executed as soon as the nurse gets a modified medication orders list. The pill dispensers may be stacked on a wheel cart or on a fixed support. Nurses perform "administration rounds" using the wheel cart with the pill dispensers on top and the patients' medical files underneath. During these rounds, the nurse administers the meds to the patient, validates the administration on the MAR (Medication Administration Record), and eventually documents any abnormality. This MAR presents the treatments on a summarized way with a temporal axis which permits to obtain, at a glance, a global, summarized view of the patients' current medication.

In the CPOE situations (H2 and H3) , a laptop on a wheel cart supports physicians order entry at bedside. The CPOE functions require two main screens to enter medication orders. Using the first one, the physician selects the proper drug. With the second one, the physician specifies the dosage. He has to enter the duration, the frequency and either a precise schedule or a global schedule (*e.g.* morning-noon-evening). The system then automatically updates the planning table and sets the specific timing for the administration depending on the organization of the ward (*i.e*. 7 am., 12 am., 6 pm.). For the display of the treatment, doctors get one screen which comes out in the form of a list of detailed orders structured with 5 columns dedicated respectively to the type of meds (oral route or injection), its detailed content, the date the administration should start and the date it should stop, and finally the status of the prescription (current, stopped or suspended). The orders and their exact time for administration appear on the nurses' care plan. As for the paper MAR, the treatments are summarized with a temporal axis which permits to obtain, at a glance, a global view of the patients' current medication. The modalities of the preparation are similar to the paper-based situations. The pill dispensers may be stacked on a wheel cart or on a

fixed support close by the laptop. If the administered drug is different from the prescribed drug, they have to document a "memo", *i.e.* a note for doctors which appears in the form of an exclamation mark in the doctors' screen.

Materials and Methods

HFE Methods

Five observers trained in naturalistic observation in complex settings conducted the observations. A first qualitative analysis of the medication ordering - administration process was undertaken. Naturalistic observation supported by handwritten time-stamped detailed field notes focused on (i) doctors-nurses' face-to-face communications about medication and (ii) interactions with the medication supports (MAR and Orders' List / paper-based and computerized). Interviews were performed with professionals to ensure a good understanding of the events and to eventually complete missing data.

In a second step, quantitative data were collected in the hospitals H1 and H2. For each ward, eight observations have been undertaken. Each observation period started with the arrival of the prescribing physician in the ward and ended with the administration of the meds to the patients. During each period, all the doctors-nurses communications about the care-providing for the inpatients were audio-taped.

Results

Face-to-face communications

The analysis amounted to 55 observations (lasting 3 to 8 hours) and 44 interviews. The observations highlight three main organizations of the doctors-nurses face-to-face communications (Table 1), thus whatever the system (CPOE or paper-based); organizations spontaneously described in the interviews by professionals.

1. The Common Round organization (CR): In the common round organization, the nurses' activities are organized so that they can participate systematically with physician to the medical rounds (one nurse or several nurses). Considering the entire prescription-administration process, the physicians-nurses face-to-face communications occur mainly during this dedicated time of the medical round. There are a two-way communications between physicians and nurses. Physician very often comment aloud their reasoning and therapeutic decision. Nurses summarize the patient's case, provide relevant information to the physicians and, sometimes, participate in the decision when they make suggestions for therapeutic changes. The very rare dialogs off the medical rounds happen only when there are unexpected changes in the situation, *e.g.* in the patient's status.

Table 1 – Percentages of the duration of doctors-nurses face-to-face communications per ward according to the communications' organization (Common Round, Briefing, Opportunistic Exchange) and the system (CPOE, paper-based).

			Scheduled		OE
			CR	B	
CPOE	H2	Card./Gastroent.	92 %	0%	8%
		Infectious disease	0%	89%	11%
	H3	Nephrology	0%	0%	100%
		Immunology	0%	0%	100%
Paper-based	H1	Neurosurgery	98 %	0%	2%
		Nephrology	0%	81%	19%
		Cardiology	0%	0%	100%

2. In the briefing organization (B), dedicated time slots are scheduled before and/or after the medical rounds where physicians and nurses participate in short daily meetings. These briefings are regularly planned at the same time so that doctors and nurses, or the extended clinical staff, can organize their activities to participate. All the patients' cases of the department are reviewed so that physicians and nurses are mutually aware of the patient's case and its evolution. The dialogs may influence the next decision making of the physicians during the medical round. Most often the briefings occur before the medical round and sometimes after, when physicians need notifying new therapeutic changes that have not been addressed during the first briefing. During the prescription-administration process, the doctors-nurses dialogs take mainly place during these dedicated times. During these two-way direct communications, nurses summarize the patient's case and physicians may comment. A few dialogs occur outside the briefing, *e.g.* when a change in the situation occurs (unexpected results, unexpected evolution in the patient's status, etc.).

3. In the opportunistic exchanges organization (OE) no dedicated time slot for physicians-nurses face-to-face communications is scheduled. Therefore, some brief dialogs occur sporadically when physicians or nurses can no longer perform their own activities with the only support of the patient record (paper or computerized): they are compelled to ask their colleague for more information. These informal communications are distributed throughout the time and the space. They are the last resources to compensate weaknesses of the systems (paper vs. computerized). Some of these brief verbal communications are initiated by physicians. They interrupt the medical round to fetch complementary information about the patient, *e.g.* "does he sleep well?" or "How much does he piss?". The information they need is not readily available whatever the technical system. But most of the communications are initiated by the nurses needing additional information to interpret unusual or modified therapeutic orders.

Medication supports

The table 2 presents the differences of each system, differences observed whatever the organization (CR, B or OE).

Table 2 – Differences in the interactions professionals / systems, depending on the type of system

Paper-based system	CPOE system
• New complementary exams or lab results can arrive anytime, professionals have then to constantly check their receipt, thus overloading the professionals • During information gathering in the patient medical record, loose sheets allow doctors to lay out all the necessary information and thus make easier the task • As the MAR is easily accessed at the patient bedside and well structured for information gathering about the current treatment, doctors systematically use it, thus making easier the information gathering • Doctors write their orders as they think them, writing orders into a paper-based system is easier/less restrictive than entering them into a CPOE system	• Alarms notify new complementary exams or lab results availability, thus efficiently guiding professionals • Finding out through the system all the necessary information is tedious (several windows and screens) and makes difficult the information gathering for doctors • To gather information about current treatment, doctors are constrained to use the order list which makes difficult the information gathering (while the MAR exists, it is not readily available to the physicians and thus is very little or not used) • The entering of unusual orders into the system is time consuming

The results show differences in the interactions between the professionals and the systems depending on the type of the system. One of the advantage of the CPOE over the paper one, is information can be updated in real time with the alarm's notifications which is a highly appreciated functionality by both professionals (doctors and nurses). However, the CPOE system fails (i) to provide ready access to a summarized view of the information and (ii) to support a rapid and easy entering of the orders.

The analyses show other differences in the use of each system, but only in one of the organizations, the OE organization (vs. CR and B) (Table 3). In this organization and for the paper-based situation, problems with notifications of changes also concern the medications changes. In the CPOE situations, in addition of being time consuming, the filling in of orders compels the doctor to enter information he doesn't usually deal with, *e.g.* the solvent of an infusion or the precise timing of medication administration, most of the time he prescribes with moments or frequencies, nurses being in charge of translating orders into suitable administration times.

Finally, none of the two systems, whether the paper-based or the CPOE, is able to efficiently support the doctors-nurses communications: in the paper-based conditions a nurse's workaround of the order list is observed and in the CPOE conditions, the "memo" functionality is not satisfying.

The results show an impact of the CPOE system on the doctors-nurses cooperative activities during the medication use process. The introduction of this type of system has the great advantage to give to the professionals an access to legible and updated information in real time as compared with a paper-based system. It has, however, some weaknesses all too frequent in currently available systems, *i.e.* the entering constraints and the failure to provide ready access to information overviews. But on looking closer, these are mainly ergonomics defects of the tool that can be easily solved and controlled.

Table 3 – Differences in the interactions professionals / systems for the Opportunistic Exchanges organization, depending on the type of system

OE/Paper-based	OE/CPOE
• The medical order list is also used by nurses to write some comments. • Doctors mainly prescribe medications during the medical round but also punctually at other times. Nurses are then stressed to miss a change in the treatment and constantly check for changes into the patients medical records • The handwriting of some doctors is illegible for nurses	• It happens that doctors miss a problem with the administration of a med (difference between what have been prescribed and administered). The "memo" is not sufficiently salient and intuitive, doctors consult it very rarely. • Some information that doctors are forced to enter can be confusing for them, *e.g.* they are not used to enter the solvent of an infusion. • The schedule of medications entered by doctors in the system is not always in accordance with nurses routines, nurses also change the timing to correspond to their rounds without checking with doctors which can be dangerous

Whatever the technical system, three main organizations (CR, B, OE) have been identified which features seem to have an impact on the coordination and communication processes. The CR and B organizations have scheduled face-to-face communications which allow each partner to take the time to understand the situation and adjust a common representation of the situation. On the contrary, the partners of the OE organization have no scheduled exchanges and interact mainly by mediated systems (CPOE vs. Paper-based) which turn out to be insufficient to support the exchanges between partners. The differences observed are the consequences of the lack of face-to-face communications; they are not observed in the other organizations (CR and B), whether with paper or CPOE.

Quantitative analysis of the face-to-face communications

The quantitative analyses amounted to approximately the same number of hours in the 5 different departments (from 36h58 to 40h05), meaning that there are no significant differences in the medication use process itself across those departments, F (4, 35) = 1.01, $p > .05$.

Table 4 - Durations of observations and dialogs according to the support of work and the organization.

System	Org.	Duration of observation	Duration of dialogs	Mean durations in minutes (SD)
Paper-based	OE	39h40	0h33	M = 4.12 (4.2)
	CR	37h33	13h10	M = 98.75 (12.2)
	B	40h05	2h15	M = 16.9 (3.3)
CPOE	CR	36h58	16h50	M = 126.25 (20.6)
	B	39h36	2h18	M = 17.25 (2.5)

As expected, there is a marked difference in the duration of the physicians-nurses dialogs according to the organization of their work (Common Rounds / Briefings / Opportunistic Exchanges) while there is no impact of the technical environment *i.e.* CPOE vs. paper-based, $\chi^2(1, N = 40) = 1.66$, $p > .05$. (cf. Table 4).

Discussion

This study addresses the question of the respective impact of organizational variables and technical environment variables on the collective aspects of healthcare work situations. The most important result of the study is the significant impact of the doctors-nurses communications organization in the teamwork. These results confirm the critical role of the face-to-face communications and of their modalities on the teamwork. For the time being the technical environment cannot support efficiently all the doctors-nurses communications. IT systems tend to acquire and present data in a mechanistic way, while conversations are characterized by the fluid and interactive notions of asking and telling, inquiring and explaining [10]. Also only a part of the communications could be replaced by information systems but not the entire communications activities. It is difficult to provide in a formal way all the information needs because they are context dependant. In routine situations, professionals share a common model of the task and so need to communicate less during an exchange. In contrast, in unusual situations a significant portion of the communication may need to be devoted to establishing a common representation of the situation. This means that during the face-to-face exchanges, partners may check with each other repeatedly throughout the exchanges that they indeed understand each other.

Although supporting more effective communication practices may have great impact on the collective activities, there remain enormous gaps in our broad understanding of the role of communication in health care delivery [8]. The great variety of communications' organizations within each hospital complicates the task. It would be interesting to provide the hospitals with a framework or an observation grid supporting the organizational characterization of their various departments before the introduction of a new IT system. The findings of this study on the three organizations need to be generalized. The issue is to identify in the work situations the determinants of the collective activities. One of them is the scheduled of face-to-face communications' slots in the work organization, and also its modalities. Indeed, exchange during the medical round and the decision making process (CR) or rapidly in the nursing room (B) is quite different. In another study, we demonstrate that the quality and extent of nurses' knowledge about the therapeutic care plans and about the drugs management may vary greatly depending on the organization of the physicians-nurses communications [11]. For example, based on the analysis of nurses' activities and confrontation interviews, we could establish that a nurse participating in medical rounds (CR) presents an extended understanding of the medical characteristics of the pathology, an extended knowledge and understanding of the therapeutic care plans and of their underlying medical rationale and finally an extended knowledge of the particular patient's medical case.

[d]*New York Presbyterian Hospital, New York, NY, USA*

Abstract

Effective communication is essential to safe and efficient patient care. We aimed to understand the current patterns and perceptions of communication of common goals in the ICU using the distributed cognition and clinical communication space theoretical frameworks. We conducted a focus group and 5 interviews with ICU clinicians and observed 59.5 hours of interdisciplinary ICU morning rounds. Clinicians used a CIS/CPOE system and paper artifacts for documentation; yet, preferred verbal communication as a method of information exchange because they perceived that the documentation was often not updated or efficient for information retrieval. These perceptions that the CIS/CPOE is a "shift behind" may lead to a further reliance on verbal information exchange, which is a valuable clinical communication activity, yet, is subject to information loss. Electronic documentation tools that, in real time, capture information that is currently verbally communicated may increase the effectiveness of communication.

Keywords:

ICU, Communication, Interdisciplinary

Introduction

Evidence linking ineffective communication in the inpatient setting to negative outcomes such as increased length of stay, increased patient harm and increased resource utilization heightens the need to understand patterns and perceptions of clinical information exchange[1-5]. Effective communication in the intensive care unit (ICU) is critical due to complex technologies, therapeutic interventions and high patient acuity [5]. In the United States, the Joint Commission has identified communication failures as the leading cause of sentinel events and listed ineffective shift report as a contributing factor[6].

Stein-Parbury and Liaschenko found that during stressful situations collaboration breaks down and professional boundaries are accentuated regarding who owns what kinds of knowledge and who is responsible for specific kinds of work[7]. The ICU is a stressful environment in which patient care is dependent on many disciplines who must simultaneously work both autonomously and collaboratively[8]. Shift work in the ICU, specifically the frequent hand-off of patient care responsibilities to a different clinician, is known to increase the demand for effective communication[9, 10]. Additionally, division of labor (i.e., distribution of activities and responsibilities), which is utilized by clinicians to increase system efficiency and overall functioning, is dependent on information exchange[8].

The aims of this study were: 1) To describe the ICU activity system in the context of interdisciplinary communication of common goals; and 2) To describe nurses' and physicians' perceptions of interdisciplinary communication of common goals in the ICU.

Background

The theoretical frameworks of distributed cognition and Coiera's clinical communication space were used to better understand clinician patterns and perceptions of the communication of common goals in the ICU (see Figure 1)[11, 12]. In the theoretical framework of distributed cognition the unit of analysis is the *activity system,* which is composed of *individuals* and *artifacts* (e.g., technology). The theory posits that the pattern of *information exchange* can drastically modify the behavior of the activity system and that the behavior of the *activity system* should be described by the patterns of information flow [11]. As opposed to traditional cognitive frameworks that only analyze individual processes, distributed cognition integrates goal directed actions and interactions of *individuals* and *artifacts,* and information exchange within an *activity system*[11].

Communication between nurses and physicians is important in the ICU because these clinicians work closely together to coordinate ICU specific patient care, communicate frequently, and are the primary users of clinical information systems (CIS) and computer provider order entry (CPOE) systems [13]. Coeira's clinical communication space framework describes the communication and information exchange activities between clinicians within the activity system according to the amount of common ground that exists between the communicators[12]. *Goal directed actions*, such as patient care tasks, and *interactions*, such as communication tasks, can be explicitly modeled, and the appropriate communication or information tools can be anticipated using the clinical communication space framework. Baggs describes ICU interdisciplinary collaboration as contingent upon the antecedent conditions of *Being Available* and *Being Receptive* which facilitate the core process of *Working Together* to achieve the outcomes

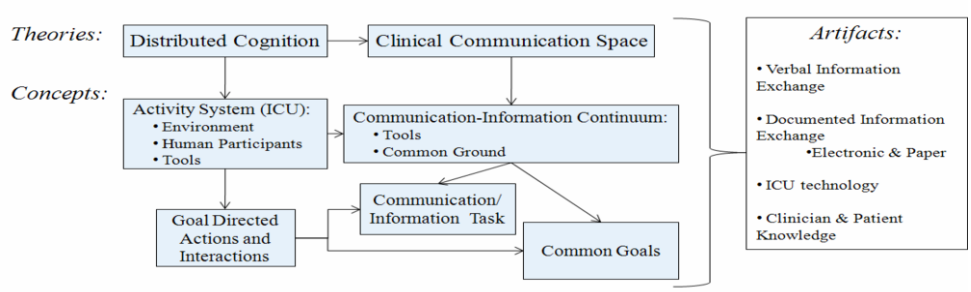

Figure 1 - Integrated Distributed Cognition and Clinical Communication Space Theoretical Frameworks

of *Improved Patient Care*, *Feeling Better on the Job*, and *Controlling Cost[14]*. The key focus of this study is *Working Together* which includes the *Coordination* and *Sharing* of patient care information in a *Patient Focused*, *Team* environment.

Materials and Methods

This descriptive study used ethnographic observation techniques, focus groups and interviews to identify characteristics of information exchange related to common goals in the ICU environment. This study took place at New York Presbyterian Hospital Columbia University Medical Center (NYP-CUMC) on the Neurovascular ICU (NICU), an 18 bed unit that specializes in intensive care for patients with neurovascular injuries. The hospital's vendor-based CIS/CPOE system supports electronic documentation of structured, semi-structured, and free text data for nurses, physicians, and respiratory therapists in the NICU.

Institutional Review Board (IRB) approval was obtained from Columbia University for all activities and informed consent was obtained from participants. The focus group and interviews, which were conducted with ICU clinicians, were held at a convenient time and place on the CUMC campus. All of the participants were compensated with a $10 cash voucher for their time. The focus group and interviews were audio-recorded and transcribed verbatim by a paid transcriptionist. The transcripts were verified against the audio-recordings by the researcher for accuracy. The field notes and interview transcripts were analyzed by the researchers for themes related to information exchange of common goals for patient care. ATLAS.ti™ (GmbH Berlin, Version 5.5.9) software was used.

We observed all clinicians who participated in interdisciplinary NICU morning rounds. During the observations the investigator (SC) observed and recorded handwritten field notes of the interactions of the entire NICU team (i.e., activity system) as defined by the distributed cognition and the clinical communication space theoretical frameworks. These interactions included conversations as well as clinicians' use of documentation artifacts, such as electronic documentation in the CIS/CPOE system and paper-based documentation. Data collection continued until data saturation (i.e., no new themes were identified) was achieved and the observational, interviews, and focus group data were triangulated for consistent themes.

We analyzed the triangulated data using distributed cognition to describe the *activity system* and the *goal directed actions and interactions* within the activity system. We also used the clinical communication space and Baggs' ICU interdisciplinary collaboration coding [14] to describe the communication and information exchange activities within the activity system (see Figure 1). Baggs' coding framework was extended where needed. The results are presented as: 1) the distributed cognition activity system description, and 2) the clinical communication space information exchange description.

Results

Clinicians were observed during NICU interdisciplinary morning rounds for a total of 16 days during the fall 2008 and spring 2009 which equaled fifty-nine and one-half hours. Each observation of NICU rounds lasted between three hours and four and a half hours. We also conducted one focus group that consisted of eight NICU nurses, one interview with an ICU staff nurse, and four interviews with ICU residents.

Distributed Cognition Activity System

Within the NICU's activity system, the individuals who were observed included the following types of clinicians: 1) Physicians (e.g., attendings, fellows, residents, and medical students); 2) Nurses (e.g., charge nurse, staff nurses, and nursing students); 3) Pharmacists; and 4) Respiratory therapists.

The artifacts used by the clinicians as information resources in the NICU were used to provide and capture information during and after ICU interdisciplinary morning rounds. During ICU interdisciplinary morning rounds, the artifacts that provided information to the clinicians were: 1) Computer terminals used by the attending, two residents and a pharmacist to provide access to the hospital's CIS system; and 2) Personal notes. These personal paper-based notes were carried by clinicians and included information written down during hand-off and throughout their shift. Personal notes consisted of the clinicians' to-do lists and the nurses' paper-based vital signs flow-sheet, as well as printed information from the CIS such as the medical administration record (MAR) and the attending's ICU note or the resident's sign-out note. During rounds, two residents sat at computer terminals and, based on the discussion, retrieved laboratory values, clinician notes, vital signs, and radiology results such as x-rays from the CIS.

Additionally, the resident who was presenting information about the patient referred to information that he or she printed

from the CIS/CPOE system as well as personal notes such as to-do lists. The patients themselves also served as an information resource during the moments that the team was in the patient's room during ICU interdisciplinary morning rounds. For example, during a given patient's bedside assessment the team also referred to data from the various therapeutic technologies in the room such as ventilator settings, intravenous medications, intravenous pumps rates, cardiac monitoring, and intracranial pressure monitoring data.

The artifacts for documentation that were used by clinicians to record the information that was discussed during rounds included paper documentation and the electronic CPOE system. The attending physician documented what was discussed by all of the clinicians who were present at rounds on the "Attending ICU note" in the CIS/CPOE system. Additionally, each one of the other clinicians were observed to hand write brief notes on their own personal papers at varying time points. The residents, using the computer terminal, continuously entered discussed orders into the CPOE system during rounds.

In addition to the artifacts that were used during rounds, the CIS/CPOE system included an interdisciplinary plan of care flow sheet. Nurses, respiratory therapists and nutritionists used this structured electronic flow sheet to document care. However, this flow sheet was not talked about or looked at during ICU interdisciplinary morning rounds. The only documents that were looked at during rounds were the "Vital Signs" and the "Intake and Output" flow sheets in the CIS/CPOE system as well as the paper-based vital signs flow sheet used by nurses. A paper-based nursing care plan was available but was not used; the nurses stated that it could be useful, but that they did not want to have to fill out any further documentation or duplicate information that they already documented in the CIS/CPOE system.

Despite documenting vital signs, medications, and fluids in the CIS/CPOE system, the nurses also documented the patient's vital signs and intravenous medications and fluids on the paper-based vital signs flow sheet that they carried around with them. The charge nurse also used a paper-based sheet that was written on and updated by each nurse during nursing rounds. This sheet contained information about each patient's diagnosis, any abnormal vital signs, intravenous lines, and plans for imaging tests (e.g., computed axial tomography, also known as a CAT scan) or surgery. The charge nurse information sheet also contained information about interventions such as the use of a cooling blanket, if Tylenol was given for a fever (a fever is a concern for neurological patients due to a link to poorer outcomes), and if intravenous medications were used to control the patient's blood pressure.

Clinical Communication Space

Clinician perceptions and patterns of interdisciplinary communication and information exchange activities were coded according to Baggs' ICU Interdisciplinary Collaboration coding framework. We found that clinicians preferred verbal discussions as a method of *Sharing* information. Therefore, to explicitly capture the clinical communication space concepts of *communication and information tasks* we added the codes *Verbal* and *Documentation Information Exchange* to the ICU collaboration framework (see Table 1). Both of these categories had positive and negative aspects, therefore, they are each represented by positive and negative clinician quotations.

Verbal Information Exchange

Overall, verbal communication was the preferred method of information exchange in this ICU. The residents used the CIS/CPOE system to retrieve vital signs, the patient's fluid balance and to make sure that orders were entered; the residents verbally asked the nurse for other information related to the nursing assessments, interventions, evaluations and coordination of care for the patient. The residents stated that they place emphasis on entering new orders in the CPOE system, yet the nurses stated the importance of verbally communicating and discussing these orders. The nurses stated that part of sharing goals is making sure everyone knows the reason for why you are making a change. "Whether or not some documentation is updated is variable, but [we try] to always verbally communicated the updates to each other in shift report."

Common goals for the patient were verbally shared by physicians and nurses during morning rounds; yet, the clinicians acknowledged that sometimes a goal was explicitly stated and sometimes it was just implied in a CPOE order or other documentation and may be missed, forgotten or not prioritized as intended. Nurses stated that if they were not present at rounds, due to conflicting patient care responsibilities at that time,

Table 1- Clinician Perceptions of Verbal and Documented Information Exchange

Verbal Information Exchange	(+) *Resident:* It's a lot faster and easier to ask 'Please, just verbally, quickly tell me what's going on.' (-) *Nurse:* It doesn't all get written down [at rounds] and the night nurses don't know, sometimes in the report it gets lost in transition...miscommunication or doesn't get passed on, and you work twelve hours with one eye closed, basically not having all the information with you. (-) *Resident:* A third of the time, usually the event is communicated verbally and the issues or treatment and results are communicated verbally again, but nothing's ever written down.
Documentation Information Exchange	(+) *Resident:* The [beside chart] of the nurse's notes…past medical history and pertinent… a log of what happened. If I know a specific event happened, and I'm trying to get more details, that's where I may go. (+) *Nurse:* Writing things down in succinct manner physically next to the patient is very helpful. Because [then] everyone's very aware of it and people start saying, "Hey, did you see them?" "No, let's call them again." It's very helpful in getting things done and communicating, because it's written down, kind of almost set in stone once something's written down. (-) *Nurse:* The computer system doesn't even remotely match what's going on with the patient. It's ridiculous; there'll be Cardizem hanging [intravenous medication] and no orders for it [in CPOE system].
(+) positive aspect of category, (-) negative aspect of category	

they would piece together the plan and determine the patient's goals from their own assessment, attending note, resident sign-out, nurse shift report, orders and unit standards "that we all know." During the observations, the charge nurse and the fellow (i.e., a physician receiving specialty training) acted as liaisons between the medical and nursing teams. There was no formal team-based meeting after morning rounds to communicate changes in plans between nurses and physicians or to come to consensus about changes in patient goals. As one nurse stated, "sometimes nursing goals and medical goals conflict; however, due to the high amount of verbal communication on the unit they often overlap." The residents and nurses agreed that "if goals are known they are used to guide the day." Therefore, the clinicians expressed that it may be beneficial to provide unified general patient goals, specific tasks and major events of the day in a simple format that is readily accessible and contributed to by everyone.

Documentation Information Exchange

Clinicians emphasized aspects of documentation in the ICU that inhibited their workflow such as patient information contained in multiple disparate sections of the EHR, and information that was not updated to reflect current patient goals. Moreover, nurses commented that orders appear in the CPOE system that were not explicitly related to the nurses perceived understanding of the common goals for the patient. One resident described difficulty in keeping the medication list accurate: "Yes, because I find that it changes frequently, that list, whether it's the drips versus the standing medications."

However, the clinicians also described aspects of the computer-based documentation that enhanced clinical workflow. One resident stated that documenting a plan "can solidify it" to help to ensure that the plan will be carried out and its progress will be evaluated. Nurses commented that 'if someone forgot to tell you the plan in report, it was wonderful if it was written in the computer.'

Our observations identified that the structured documentation in the CIS was typically supplemented by CIS free text notes written by nurses and CIS sign-out notes written by residents at or near the end of their shifts. These notes included information that may have been documented in a structured format in other parts of the CIS, but summarized the structured data and provided additional contextual information in order to "tell the story" of the patient and the patient care that was provided during that shift.

Discussion

Computerized systems may increase the effectiveness of communication within the nursing or medical discipline [15, 9]. However, the integrated distributed cognition and clinical communication space analysis demonstrated the perceived lack of effective and updated electronic documentation artifacts within the ICU activity system that was examined. Limited use of electronic documentation restricts the ability of clinicians to establish common ground through the CIS regarding their *goal directed actions and interactions*, *communication and information tasks*, and *common goals* of patient care. Our analysis suggests that when the CIS does not facilitate clinicians establish common ground they prefer verbal information exchange.

Based on the clinicians' statements during the focus group and interviews, information contained in the CIS is often perceived to be a *shift behind* (e.g., night shift or day shift) and includes only the clinical care that has already been provided to the patient. Therefore, the current structure and content of the documentation tools in the NICU may not be sufficient to capture the information exchange of common goals that occurs during and in between ICU interdisciplinary morning rounds. The perceived lack of updated documentation may increase clinicians' reliance on verbal communication. For instance, if the clinicians perceive that other clinicians are not updating the electronic documentation frequently they may wonder if frequently updating the electronic documentation is an efficient use of their time during their shift in the fast paced and complex ICU environment. These perceptions likely influence clinicians' behavior to electronically document patient information at the end of their shift or to omit information that had been verbally exchanged from the electronic documentation. Kim et al., also found that the restrictions imposed by the CIS developers caused nurses to omit many information layers and data categories that would have represented greater contextual information that was useful for clinical care as well as for data reuse for administrative and research purposes [16].

Clinicians' continued reliance on personal paper-based notes suggests that the CIS may facilitate establishing common ground amongst the clinicians. One of the intended useful roles of a CIS at the point of care is to provide clinicians with access to shared information regardless of constraints such as their location or the time of the day. The sharing of paper based documentation is limited by constraints such as the location of the documentation or the shift worked by the clinician that is in possession of the paper documentation.

Of note, the clinicians that were interviewed appreciated the potential benefits of electronic documentation such as increasing common ground regarding the patient's plan of care, preventing information loss, and increasing the opportunity for information retrieval. However, the continued use of personal paper-based documentation by clinicians and their preference for verbal communication, despite their acknowledgments of the potential benefits of electronic documentation, are evidence that clinicians are ignoring aspects of the CIS/CPOE tools that do not fit into their clinical workflow.

Despite the clinicians' perceived limitations of the CIS/CPOE system to support ICU communication and information exchange activities, the clinicians continued to use the CIS/CPOE system; however, they supplemented the system by implementing verbal information exchange conventions. These verbal conventions were used to verify information that was updated in the CIS/CPOE system in an effort to ensure the quality and safety of patient care. For instance, the nurses stated that CPOE orders may only imply what the related patient goal was; therefore, if a goal related to an order was not previously discussed or documented the nurses' verbal double check may be the only form of verification that the order was entered as intended. In a previous study we found that nurses perform these double checks by determining the physician's rationale for an order as a method to assess the safety and ap-

propriateness of the order [17]. These finding about the clinicians' use of verbal double checks relate to Hazlehurst and colleagues conclusion that multiple representations, or redundancy, of information in the ICU increases robustness of the system and ensured correct functioning [18]. Including contextual clinical information linked to CPOE orders or nursing actions, such as the rationale or an explicit patient goal, may provide the multiple representations that may be sufficient as a double check. Moreover, the clinicians' free text documentation in the CIS provided contextual information and summarization of the interpretation and meaning of the structured data points in various parts of the CIS. Clinicians' discussions may inform the "story of the patient" that is told in the free-text documentation; additionally, a clinician may "tell the story" of the patient in free-text documentation because once his or her shift is over there likely will be no further opportunities to discuss and convey summarized and contextual information about the patient with other clinicians who may care for the patient. According to Coiera's [12] clinical communication space theoretical framework, information that is routinely verbally discussed during rounds or documented in free-text notes that summarizes and contextualizes patient information to "tell the story" of the patient, may be ripe for an automated information tool.

The limitations of this study are that the observations were conducted on one NICU and that all of the clinicians that were interviewed or participated in the focus group were from one hospital. Therefore, some of the findings may not be transferable to different ICUs, different types of patient care settings, or other hospitals. Additionally, we did not conduct any observations during the night shift in the ICU. However, the data saturation and triangulation of the observational, focus group and interview data increase confidence in the discussed themes and conclusions drawn from this study.

Conclusion

The large amount of information that is verbally exchanged amongst clinicians is evidence that clinicians have not harnessed the CIS/CPOE tools available for their maximum use of information exchange. According to the clinicians observed and interviewed, CIS/CPOE documentation is a *shift behind* and information retrieval is not efficient, leading to a further reliance on verbal information exchange. Moreover, verbal information exchange is subject to information loss.

Our data indicate that the current documentation tools in the NICU may not be sufficient to capture the interdisciplinary communication of common goals that occurs during, and in between, ICU interdisciplinary morning rounds. Therefore, future research should aim to further understand and meet the need for CIS/CPOE documentation to support verbal information exchange in the ICU in real time.

Abstract

Medication errors are of major concern in most countries. The European PSIP project aims to identify and prevent medication errors by enabling data mining and designing contextualized decision support functionalities using a human factors engineering approach. To create a basic understanding of the work practice in the medication process members of the staff in a cardiology department in a Danish hospital were asked to take pictures of their workplace. The pictures were used as a memory trigger in a subsequent interview. Furthermore a video based observation of a full day of work was carried out. In this paper the methodological considerations and experiences are presented and discussed.

Keywords:

Adverse drug events, Human computer interaction, Video analysis, CPOE.

Introduction

Adverse Drug Events (ADE) due to medication errors and human factors are a major public health issue. They endanger patient safety and cause considerable extra healthcare costs. Decision support should assist in reducing the incidence of preventable ADE, by providing health care professionals and patients with relevant information and knowledge. The efficiency of the relevant feedback is however impeded by two major drawbacks:

- Lack of reliable knowledge about ADE
- Poor ability of IT solutions to deliver contextualized knowledge focused on the problem at hand, aggravated by a poor consideration of causative human factors

The European project PSIP (Patient Safety through Intelligent Procedures in medication) aims to identify and prevent ADE [1]. Data mining and semantic mining of structured hospital data bases in France and Denmark will give a list of observed ADE with frequencies and probabilities, thereby giving a better understanding of potential risks. The main objective of the project is to develop innovative knowledge based on the mining results and to deliver to professionals and patients contextualized knowledge fitting the local risk parameters in the form of alerts and decision support functions.

To enable the design of alerts and decision support functions in a contextualized form it is essential to have a deep understanding of the medication process as it is performed in daily clinical work. The present study surveys the medication process in a cardiology department in a mid size hospital in the Capital Region in Denmark.

Methods

In earlier work practice analysis it has been shown that there is a fundamental difference between what people say they do, what they think they do, and what they actually do [2]. What the users say and think they do to perform their work tasks can be investigated by interviews [3], but to explore what they really do and how they do it can best be revealed by close observation of their work over a period of time. The combination of interviews and observation studies is a good means of identifying how work tasks are adapted to fit the particular contextual setting [4].

In this study a nurse and a physician were interviewed to investigate how they performed the three stages of the medication process: prescription, dispensing, and administration. Two weeks prior to the interviews the two staff members received a disposable camera and were asked to take pictures of situations from daily works practice they felt important. The semi-structured interviews started with open questions about each phase of the medication process, prescription, dispensing and administration. The two staff members were asked to explain which devices and artifacts they used in each phase, what knowledge they applied, and how the tasks are organized.

Their response (the light post-it notes in Figure 1) were categorized and validated during the interview. These categories correspond to a general technology concept [5]. When they could not think of any further issues under the mentioned categories they were presented with the pictures they had taken with the camera.

The pictures triggered their memory with additional issues (the dark post-it notes in Figure 1). Apart from identifying the elements included in the medication process the nurse and the physician were also asked to explain the actions taken in performing the tasks. Hence the interviews provided a description of how the staff perceives their work practice in the medication process.

To get information on how the medication processes really are performed and the technology involved in the contextual setting we observed two nurses and the physician during a full days work. The observations were recorded on three video cameras.

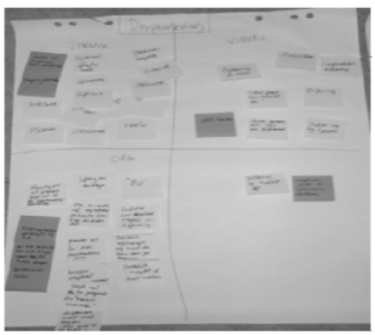

Figure 1 - Categorizing issues mentioned during interview

As a pragmatic validity and reliability check the approximately 18 hours of video was subsequently reduced to 20 minutes representing the most important situations in the prescription, dispensing and administration phases. The 20 minutes video recording has been approved by the staff, as representing this particular day at the cardiology department.

The full length video recordings were organized according to what phase of the medication process it concerned. In particular the physician work practice in the prescription phase was coded using a grounded theory approach. A first attempt to detect situations where decisions were made was given up, because it was impossible to detect precisely when single decisions were made. Instead we could identify when new information was obtained, from what source, and where it happened. Hence the physician's round with seven patients was coded with respect to when information was obtained from:

- a digital artifact
- a paper artifact
- a nurse
- the patient
- another source

The information obtained from coding was used to create a graphical representation to model the health professional's information seeking and processing. This representation graphically depicts over time the location of the health professional, the artifacts involved and the conversions that took place. An excerpt representing the interaction of the physician with a patient on a round is shown in Figure 2.

Results

The photo supplemented interview method and the video observation method for studying work practice in the medication process has been carried out without practical complications. They both produced very rich data as explained in the following.

The summarized results of the interview with the staff nurse are shown in Table 1. Each of the three phases in the medication process--prescription, dispensing and administration are listed in columns. The general technology framework is used to categorize all the issues and elements that came up. The elements that were mentioned during the conversation in the first part of the interview are printed in regular font; whereas the elements that were added after the nurses were presented with the photos they previously had taken with the disposable cameras are printed in italics. In the bottom row of Table 1 the actions taken during each medication phase are described.

The video recordings from the three cameras added up to more than 18 hours and give a very rich picture of what is really happening during a normal day at the department. The raw material has been edited and reduced to 20 minutes that can be used for presentation to external audiences, which has been approved by the staff at the cardiology department.

The video recording has been coded and graphically represented using the diagramming method described above in the Methods (see Figure 2). All the video for the physician has been coded and the video for the nurses in its full length will also be coded to detect and investigate important variables of context determinants. The aim of this analysis is to guide the design of decision support functionalities and their contextualization.

Discussion

When interviews are used as the data collection method voices are typically audio recorded for later transcription. Later the respondents validate the transcriptions, which subsequently are analyzed with respect to specific aspects. In the present study the analysis was performed simultaneously with the dialogue with the respondent, and the validation of the categorization was done at the end of the interview. This allowed us to correct potential misinterpretations during the interview. However, a potential disadvantage is that the respondent starts to respond according to the categories instead of just answering the questions.

The respondents own photos proved to add value to the interview. Nine new elements came up after the pictures were presented to the nurse, and in the description of how they performed in the medication process were remarkably enriched by the presence of the pictures.

The use of video recording for observing work practice differs from other uses of this media in a number of ways [6]:

1) The activity filmed does not happen for the sake of the recording. It has similarities with surveillance, but differs from test situations such as traditional usability evaluation.

2) The actors are aware that they are being filmed. In most cases the actors has been involved in the preparation of the recordings and have agreed to participate, which distinguishes it clearly from surveillance.

3) The actors are not paid or in any way bound to a particular obligation during the recording.

4) The recording happens as a part of a change process to the actors' work practice. In the present case the staff has an obvious interest in contributing to improvement in patient safety and the reduction of ADE's.

The greatest advantage of using video for observations is that this media can catch work practice situations visually as well as recording sound. The video document enables deep analysis because repetitive playbacks facilitate the study of essential details in the work practice – details that were imperceptible at first sight. The video recording is, however, not identical to the authentic situation. It will always be a reduction of the real, and not a completely accurate reproduction. Firstly the video media has a selective view limiting what is possible to observe, and secondly the sound quality can be reduced which means that pieces of information can be lost. Thirdly the space of experience is reduced from 3-D to 2-D. The most significant reduction however is the total absence of smell and atmosphere in the location, which can have significant influence on the interpretation of a communication process.

Qualification	• Basic nursing • Knowledge from errors • Experience • Older nurses • *CPOE-course*	• Locally acquired skills • Experience • Alert with toxins • Wonder and double check • *CPOE training*	• Locally acquired skills • Experience • *CPOE training*
Organization	• Patient • Other nurses • Physician • Lab technicians • Pathology lab • X-ray • Blood bank	• Asking colleagues • Quietness in medicine room • Dispensing for the whole day depending on time available • *Check off with the mouse instead of bar code*	• Independent work • Planning as the day pass • One patient at a time • Watch the patient take medicine
Outcome	• Information sheet to patients • *Health status improvement for patient*	• Medicine in the cup • Medicine in accordance with prescription	• Medicine administered • Changes recorded in CPOE
Action	Decisions on prescriptions made during • Discussing patients during board round • Collaboration with physician using the CPOE system and other information systems in the office • Communicating with the patient, the physician and other colleagues	• Find the patient in the system • Print out label with patient ID • Identify the medicine • Find it on the shelf • Identify it by the barcode • Dispense the prescribed dose • Check for dispense • Put the glass on trolley	• Log in on PDA • Drive the trolley to the bed room • Find the patient • Read the bar code • Check the identity • Explain the medicine • Watch the patient take the medicine

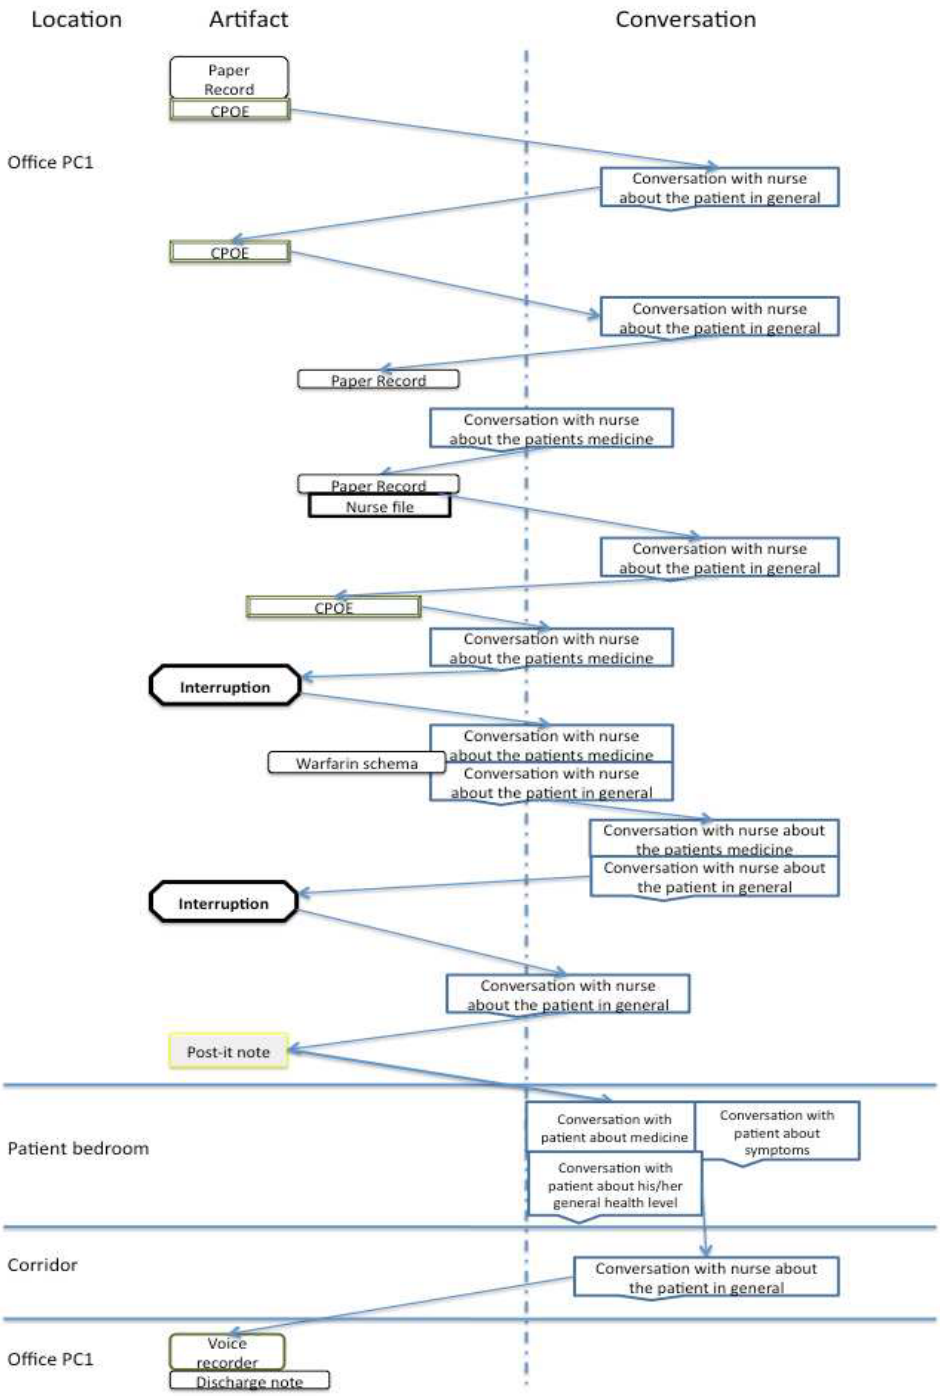

Figure 2-Graphic representation of information seeking with a patient and processing during a round

One of the perils of using video for analyzing work practice is that it can have a seductive effect. This seems to appear in at least three different forms [6]:

1) In the illusion that what you see is objective data.
2) In the risk of viewing it as entertainment.
3) In the temptation to ascribe the actors' motives and feelings.

The seductive effect in terms of objectivity often happens when hours of real time recordings of every day work practice seen through a particular lens are fragmented and analyzed by several independent researchers. They can identify typical work actions, quantify them and compare results. In this situation it is often forgotten that the data has already been edited: positioning of the camera has been determined, timing of the recording and equally important, those who are behind the camera often come out of the same community of practice as the staff being observed.It can sometimes be difficult to yield to the temptation to let unintentionally funny situations slip through the editing process or to focus on such situations in the analysis. It is often the unexpected, the disconfirmation of expected patterns that attracts attention. Particular consideration of ethics is essential to maintain video recording as a scientifically sound methodology [7].

In the present study we asked the physician and the nurses we primarily followed to think aloud. We did not want them to talk to the camera, or explain what they did, but just to say what they were considering in their work. This seemed to work very well, and it appeared to be very easy for them to do because they are used to collaborating in their work tasks (i.e. during the prescription phase the nurse and the physician constantly communicate about diagnoses, development in health condition, observations of patient behavior and things that must be done).

A question often discussed is the degree to which people are influenced by the presence of a camera, and if it makes any difference if there is an operator behind the camera [8]. After all it boils down to an empirical question that must be investigated on each occasion. From viewing the recordings it is clear that we can distinguish when the work performed is influenced by the presence of the camera. Often the observed person starts to talk directly to the camera, when he/she discovers it or abruptly changes behavior. In general however it is our experience that the observed staff members very quickly habituate to the camera, and the presence of the camera does not bias the observations in any significant way.

In the present study it has been clearly demonstrated that the interviews – supported by the respondents' own photos resulted in a clear and detailed description of how the medication process is performed. The descriptions obviously follow the rules for how medication processes are supposed to happen. The nurse describes the process as it is taught at the nursing school. However, from the video recordings of a single day in the department it is clearly shown that the formal medication process is often over-ruled by shortcuts and workarounds. But it is also clearly documented that every case of over ruling is accompanied by a rational argument in terms of efficiency or considerations about quality of care for an individual patient.

Conclusion

Analysis of work practice of medication processes using video in combination with interviews supported by pictures taken by the respondents has proven to be a very powerful tool to obtain an understanding of what is really happening during the medication process. The methodological discussion has also exposed how important it is to be critical in the detailed analysis of the rich and comprehensive data collected.

Acknowledgement

This research is supported by the European Commission, Seventh Framework Programme, Strategic Objective/Theme: ICT-1-5.2. Grant agreement no. 216130. We want to thank Sanne Jensen for organizing the contact, and the staff at the department of internal medicine M3 at Frederiksberg Hospital in the Capital Region, Denmark for their participation.

Steps towards Single Source - Collecting Data about Quality of Life within Clinical Information Systems

Fleur Fritz[a], Sonja Ständer[b], Bernhard Breil[a], Martin Dugas[a]

[a] *Department of Medical Informatics and Biomathematics, University of Münster, Germany*
[b] *Competence Center for the Diagnosis and Therapy of Pruritus, Department of Dermatology, University Hospital Münster, Germany*

Abstract

Information about the quality of life from patients being treated in routine medical care is important for the attending physician. This data is also needed in research for example to evaluate the therapy and the course of the disease respectively. Especially skin diseases often negatively affect the quality of life. Therefore we aimed to design a concept to collect such data during treatment and use it for both medical care and research in the setting of dermatology. We performed a workflow analysis and implemented a designated form using the tools of the local clinical information system. Quality of life data is now collected within the clinical information system during treatment and is used for discharge letters, progress overviews as well as research about the treatment and course of disease. This concept which contributes to the single source approach was feasible within dermatology and is ready to be expanded into other domains.

Keywords:

Quality of Life, Pruritus, Single Source, Clinical Information System

Introduction

Medical care and research aim to enhance the quality of life (QoL) of patients. Documenting quality of life in routine healthcare and reusing this information for research should therefore be fundamental. This reuse of routine healthcare data for research purposes, which reduces the documentation workload and enhances the interaction between care and research, is an example of the *single source* approach.

One objective of single source in medical informatics is the rapid innovation transfer between medical care and medical research which implies the joint use of data collected at a single data entry point and the exchange of it respectively [1]. Although data collected during medical care might serve different purposes than data for clinical research [2] the data collected during medical treatment is valuable also for research purposes and vice versa. It should not only be collected for a single purpose especially not only for administrative purposes.

Regarding quality of life this data is not only used for medical care and research but also needed to account for new cost-intensive medical treatments to third party payers. The value and effect of the medical treatment is measured by the related benefits for the patient and one instrument to measure patient welfare as a consequence of medical treatment is QoL [3, 4]. Scores related to QoL therefore provide an instrument to quantify the improvement or impairment of the health of patients through health care interventions.

The analysis of QoL information is relevant for various medical domains. In the medical domain of skin diseases for example many studies related to psoriasis or atopic dermatitis showed that the quality of life is negatively affected [5]. A main symptom which dramatically affects the QoL is pruritus [6]. However vertical data collection about various dermatoses, especially chronic pruritus, and longitudinal data collection about the course of disease and improvement of QoL is still scarce [7].

The "Competence Center for the Diagnosis and Therapy of Pruritus" (in the following simply called pruritus competence center) which is part of the dermatology department at the university hospital of Münster is currently studying how out- and inpatient medical care influence the QoL for patients with chronic pruritus. A common instrument regarding quality of life in this field is the dermatology life quality index (DLQI) [8] which is also used in the course of various studies at the pruritus competence center. For routine medical treatment it was shown by Salek et al. [9] that the systematic assessment of patient QoL is beneficial and should be a routinely measured parameter in dermatology.

The collection of data about QoL however implies technical and organizational challenges. A recent study shows that the routine documentation workload of medical staff already takes about 25% of their total workload [10] and that usually does not include data about QoL. In the pruritus competence center for instance one medical doctor has an average number of 12 patients per day, most of them also being enrolled as study patients for whom the QoL is scored throughout the study period. The data collection will have to be integrated into the

clinical routine workflow and therefore into the clinical information system (CIS). For the medical staff it will need to add value in order to be accepted.

We therefore aimed to develop a single source concept to collect and use data about quality of life and to assess the technical, organizational and clinical feasibility of that concept. As a pilot setting the department of dermatology and the DLQI to score the quality of life were chosen.

Materials and Methods

Workflow Analysis

We analyzed the process of the current documentation concerning users, equipment and forms in the department of dermatology using standard methods of business workflow analysis [11]. The analysis was done through unstructured interviews with doctors, nurses and administrative staff and through on-site observations of the clinical routine workflow. The forms were analyzed with respect to their format, data structure and use. To evaluate user acceptance we applied unstructured interviews and measured the number of used forms.

Pilot Setting

The DLQI, which was developed by A. Finlay, is a questionnaire comprising ten items and is used for ongoing scoring of life quality in dermatology [12]. It was used for various studies in the past and proofed to be adequate to provide reliable data for the quality of life [8]. Therefore we chose this instrument and evaluated it for its use and implementation within the local clinical information system ORBIS® [13]. As pilot department we chose to work with the pruritus competence center as they already have experience using the DLQI.

Implementation of forms within the clinical information system

The electronic form was implemented with the integrated form designing tool of the local clinical information system called ORBIS® Form Designer [13].

The electronic form was designed in the same format as the original paper form and can also be printed for the patient as the corresponding print template is attached.

Querying the results of the electronic form

All data within and attached to the form can be queried with the integrated query tool of the local clinical information system called ORBIS® Report Generator [13]. Using this tool the overview of all patient scores was parameterized by querying data from the completed forms for each patient and displaying date, commentary field, score and meaning of the score (see Figure 1).

In addition the single values for each item can be extracted and the query for all patients can be exported into csv (comma separated value) format in order to be used for further analysis. All query data is pseudonymized before being exported.

Results

The DLQI form and its workflow were analyzed, parameterized and implemented in the productive database of the local CIS within less than a week. The following Table 1 shows the application areas of the DLQI score in the past (Before) and with the integrated electronic form (After). The results are referred to throughout this section and the following discussion section.

Table 1 – Application areas of DLQI Score

Application area	Before	After
Patient inserts data into CIS	No	No
Documentation of QoL for outpatients	Yes	Yes
Documentation of QoL for inpatients	Yes	Yes
Progress overview of QoL over time for outpatients	No	Yes
Progress overview of QoL over time for inpatients	No	Yes
Transfer of QoL information into doctor's letter for outpatients	No	No
Transfer of QoL information into discharge letter for inpatients	No	Yes
Reporting functionality for research purposes	(Yes)	Yes

Application area = Areas in which the DLQI score is used; Before = Available before the implementation; After = Available after the implementation

Past Documentation Workflow

In the course of out- and inpatient medical care QoL by means of the DLQI is scored for every outpatient visit and for inpatients at admission and discharge. Shortly before the consultation the patients receive the paper form of the DLQI and have to answer the 10 questions which relate to how much the skin problems affected their lives in the past seven days.

In the past patients answered the questions on paper forms which were handed to the treating physician during the visit. This paper form was then filed in the paper patient record. The score was calculated manually and entered into a separate excel-based database for research purposes.

New Documentation Workflow

Two doctors of the pruritus competence center were trained as key users to use the form in the pilot phase who then trained other users.

Progress Overview DLQI

Date	Status Commentary	Score	Meaning
6.10.2009	after treatment	5	small effect
24.9.2009	at discharge	8	moderate effect
12.9.2009	Status improved	10	moderater Effekt
2.9.2009	at admission	17	very large effect
24.8.2009	during treatment	12	very large effect
9.8.2009	before treatment	15	very large effect

Figure 1- Overview of DLQI Scores for a patient

Date = Date of data collection; Status commentary = Text chosen from a catalogue in the form about the status at the point of data collection; Score = calculated DLQI score; Meaning = Meaning of the score, effect on the quality of life

The treating doctor or medical assistants now insert the completed paper forms received from the patients manually into the electronic form in the CIS for the respective patient. As there are only 10 items in the questionnaire it was decided for the pilot phase to be faster and easier to manually enter the answers instead of implementing a possibility to e.g. scan the completed questionnaire and automatically insert the answers in the electronic form.

Through the implementation of the electronic form the following additional features were added which is also reflected by Table 1:

- The date of the data collection is preset with the date of creating the form but can be changed in case the electronic form is completed at a later stage.
- A catalogue to enter a status was added. Here it is possible to select a commentary about the state of the patient and about the point in time the form was filled in (e.g. At admission, At discharge, Status improved, etc.)
- The score will be calculated automatically but only after all questions are answered. For every question there is the possibility to answer "not relevant" which equals 0.
- Besides the score as a number also the meaning of the score, and thus the effect on patient's life, will be calculated and displayed automatically next to the score. In case the effect is very/extremely large the text is displayed in red to highlight the severity.
- For every form saved in the electronic patient record the reference shows the date of data collection, the score and the meaning of the score.
- Within the form it is possible to open an overview of all previously collected scores for that specific patient with their dates and meanings as shown in Figure 1.
- A text module was created in order to takeover data from the DLQI into the discharge letter or other communication documents.

A query like the extract in Figure 2 showed that in the course of two months the form was used 104 times for 45 inpatient and 59 outpatient cases for a total of 86 patients. The average time needed to complete the form was 1 minute and 10 seconds with a standard deviation of 40 seconds. After 6 months of use more than 650 forms were documented for 139 inpatient and 511 outpatient cases for a total of 460 patients.

The DLQI score from the same form was used by means of a text module in the discharge letters of 14 patients in the first two months.

The users reported that the overview of all scores for a patient (Figure 1) was looked at frequently however it is not verified through system data because this form does not have the option to be saved in the database.

A report similar to Figure 2 which queried all single items as well as other related patient data was generated and can be looked at directly in the system or exported in csv format. In that way it can also be used in an already existing separate research database at the pruritus competence center for further study purposes. For example DLQI scores for all patients can be imported into the current excel database using a macro.

Whether there are more complete forms now compared to the number of completed forms before the implementation no reliable data was found.

In unstructured interviews the trained doctors were asked about their experience with the electronic form after the first week and the first month of its use and were satisfied with the usability and added functionalities of the implemented solution. After 6 months the form is still used regularly for every patient visit.

Discussion

The electronic version of the DLQI is used for the medical care visits in the area of pruritus for out- and inpatients and will provide data for research purposes. The form was easy to implement, had a good acceptance and the added functionality was found to be very useful by the users. The time needed to insert the data from the paper questionnaires was relatively short and well accepted. Besides in the end no additional time was added to the process as the time which was needed before to calculate the score is now used for the manual insertion.

Because of the availability of the score and its meaning through text modules within the CIS this kind of information about quality of life was made available for the first time within the discharge letter. This was found to be very useful as it is now communicated to other treating physicians. Therefore it is planned to use this text module also within other types of communication documents.

The progress overview of all DLQI scores for a patient can now be used during medical care to observe the progress and in retrospective studies for various research questions. In addition the structured availability of quality of life data can serve to proof the need of special treatment towards third party payers.

It is also possible to generate queries that span all patients and include patient/case-related data. By using those queries research findings could be supported with data extracted out of the clinical information system. In addition the export of all queried data in csv format can be used for further research in various studies in which the DLQI is needed as a parameter. Before the implementation of our concept QoL data was only manually inserted in a separate research database whenever it was needed. Therefore in Table 1 the research reporting functionality is shown in brackets. For vertical studies it is planned to implement the form in the whole clinic within the next months in order to collect more data in the different domains of skin diseases.

This shows that a reasonable amount of QoL data will be collected through a simple form implementation, which serves different purposes in medical care and research. Through this prototype in dermatology a common concept is now available to integrate QoL information within routine treatment.

Limitations and future prospects

One limitation is that the patients have to fill in the questionnaires themselves. The DLQI is a patient reported QoL but they do not have access to the CIS and hence another person has to enter the respective data. Table 1 shows that this was neither possible before nor after the implementation of our concept. Therefore another future topic will be an evaluation about other ways to insert data, e.g. through scan mechanisms, digital pens or mobile devices with or without touch screen functionality. The challenges here are firstly that for the patient those applications need to be as simple and easy to use as the paper form. And secondly most CIS vendors ask high prices for interfaces even to such simple applications as the electronic format of a patient questionnaire which not all clinicians are willing to pay. However once a feasible method is found to insert such data into the CIS it might also be possible to link data from other healthcare providers like the general practitioner or transferring hospitals.

The fact that another person has to enter the data into the system also limits the timeliness of the availability of data. It is not possible yet to transfer the QoL data into the doctors' letters of outpatients as shown in Table 1. This is because those letters are written during or directly after the visit and not in all cases the QoL data has already been entered until then. Other mechanisms of timely data entry will have to be analyzed as already stated above.,

We also were not able to find out yet whether there are more complete forms now than before. Although through a plausibility check all forms need to be complete in the electronic form in order to show the score there can still be incomplete paper forms coming from the patients and thus also incomplete forms without a score in the system. However, we did get told that the form is now used regularly for every patient visit which was not the case before.

Within the dermatology department a next step is to implement another scale used during pruritus treatment to score the pruritus intensity. This can then be evaluated against the QoL score. Also the QoL data will have to be integrated with treatment documentation which so far is only done within the paper patient record. This way measuring patient benefits in the course of the therapy can directly be set into relationship with the treatment. Another step towards the integration of routine and research will be made.

To further validate the general concept to collect QoL data during routine medical treatments and use that information for both care and research purposes, we will implement our concept in other medical domains in the coming months. For example the same method of implementation was already applied for other similar scores, e.g. depression scales like Hamilton and Young Mania Rating Scale in psychiatry.

However, in that case the scores were not directly related to quality of life but to monitor the severity changes under treatment. Apart of the other medical domains we will also need to bring this solution into other hospitals with different clinical information systems to proof the generalized solution.

Conclusion

Data about QoL can now be extracted directly from the clinical information system and be used in the routine medical care as well as for research purposes. Thus the collection of QoL information through a single source approach is feasible and well accepted in a university hospital setting.

Competing Interests

The authors declare that they have no competing interests.

Acknowledgments

Thanks to A. Finlay who supports the implementation of DLQI in daily medical care.

Methodology of integration of a clinical data warehouse with a clinical information system: the HEGP case

Eric Zapletal[a], Nicolas Rodon[a], Natalia Grabar[ab], Patrice Degoulet[ab]

[a] *Department of Medical Informatics, Georges Pompidou University Hospital, Paris, F-75015 France*

Abstract

Clinical Data Warehouses (CDW) can complement current Clinical Information Systems (CIS) with functions that are not easily implemented by traditional operational database systems. Here, we describe the design and deployment strategy used at the Pompidou University Hospital in southwest Paris. Four realms are described: technological realm, data realm, restitution realm, and administration realm. The corresponding UML use cases and the mapping rules from the shared integrated electronic health records to the five axes of the i2b2 CDW star model are presented. Priority is given to the anonymization and security principles used for the 1.2 million patient records currently stored in the CDW. Exploitation of a CDW by clinicians and investigators can facilitate clinical research, quality evaluations and outcome studies. These indirect benefits are among the reasons for the continuous use of an integrated CIS.

Keywords:

Clinical data warehouse, Clinical information system, Heterogeneous data integration, Data security.

Introduction

Clinical Data Warehouses (CDW) were defined in the early 90s as subject oriented, integrated, time-variant, non volatile collections of data used in support of management decisions [1]. They have been extensively used in the industrial field [2] and much more recently in healthcare. CDW now play an important role when addressing issues related to the integration of heterogeneous databases, considered essential for biomedical research [3]. For example, new types of data, arising from tissue bank management systems [4] or biomedical research [5], need to be integrated with legacy data sources to promote networked or translational research.

Although there are examples of studies demonstrating the benefits of using a CDW for clinical and biomedical researches [6-8], the direct reuse of clinical information systems (CIS) for this purpose is still very rare [9].

Here, we present the methodology used at the Georges Pompidou European Hospital (HEGP) to implement a CDW that is closely integrated with the hospital CIS.

Materials and Methods

The HEGP clinical information system

HEGP is an 890-beds university hospital in southwest Paris, France. The total number of employees is 3,200, with 400 full-time equivalent physicians. The mean number of inpatient admissions/month is 4,700 and of outpatient visits/month is 18,000.

The HEGP CIS is built upon on a component-based approach [10]. The healthcare-related components include the patient ADT, healthcare record (EHR), and act management (CPOE) components from MEDASYS®, and an appointment-resource scheduling component ONECALL© from McKesson®. Healthcare components are integrated through an enterprise application integration platform (EAI) developed by THALES® including a reference manager where the different concepts and their relationships are declared. The CIS is accessed from the 3000 PCs, laptops, and thin clients through a common portal associated with a HL7/CCOW manager and a security component where user access rights are described.

A top down design approach

The deployment of this CDW is a four-year project that started in 2008. One of its objectives is to establish a global methodology for integrating a CDW into comparable French institutions. Using a top-down approach (Table 1), we decided to distinguish four domains or realms (technical, data, restitution and administration) in which we successively: 1) model UML use cases related to the CDW design; 2) analyze compliant technological frameworks, and 3) implement functionalities with selected tools.

This approach is described in detail below.

Table 1- HEGP top-down approach to integrate clinical data warehouse into the clinical information system

	Technical realm	Data realm	Restitution realm	Administration realm
UML use cases	To ensure security and data protection To optimize usability of IT tools To tune data flows and data volumetry	To make source data available To make target data available	To design and broadcast CDW objects	To manage the life cycle of CDW objects
Technological frameworks	French National body for security recommendations; strong reversible encryption algorithm Open source software; collaborative developments Database mirroring	Navigation through database models; business layers analysis Mapping of data sources to target CDW schema; datamart creation	Business intelligence solutions; enterprise content management systems	Help desk system
Implementation tools	Bouncy Castle® java library I2B2® framework ORACLE® utilities	SchemaSpy; SAP®/BO Universes ORACLE® (materialized) views; Talend®/OS ETL jobs; DocuWiki	SAP®/BO reports; KaliTech®/Kalidoc; I2B2 client	Peregrine®/GPS

UML use cases

The technical realm

The technical realm concerns the deployment of CDW hardware and software infrastructures. We have identified three corresponding top-level use cases:

- To ensure security and data protection: we assume that users with high level permissions (physicians for example) are allowed access to all data concerning their patients, but that users with low level permissions (statisticians for example) should only have access to anonymized data. We refined these use case by analyzing each of the recommendations of the French coordinating body for privacy and security (CNIL) and their impact on every CDW activity [11].
- To tune data flows and database volumetry.
- To provide easy-to-use IT tools: one of the main objectives of the CDW project is to facilitate user access to the clinical data. Therefore, the ergonomics and the usability of the IT tools provided are very important. In particular, they must solve the "not enough time" issue [12].

The data realm

The data realm covers the management of the data sources that feed the CDW, including how data are modeled, accessed, and integrated into the CDW. We identified two corresponding top-level use cases:

- To make the source data available: this use case concerns physical access to data, model documentations, potential reverse engineering techniques and cooperation with applications vendors.
- To make the target data available: in this use case, the focus is on the capacity of the CDW model to support data analysis and design of new objects (reports, indicators, etc.), i.e. to move from a storage/access-oriented data model of operational medical applications to the analysis-oriented model of a CDW.

The restitution realm

The restitution is related to the manner in which users have access to the CDW objects and how new information is generated in the CDW. We identified one top-level use case in this realm:

- To design and to broadcast reports.

The administration realm

The administration realm deals with the exploitation (supervision, parameterization, evolution and maintenance) of the CDW objects. From a quality of service point of view, with the objective of managing the activity of the CDW as a service provided by the IT team to the end users, the main use case is:

- To manage the life cycle of the CDW objects

Results

CDW technological frameworks and implementation tools

The technical realm

To fulfill the constraints related to source code accessibility and collaborative development possibilities, we decided to focus on Open Source software components, whenever possible. A CentOS/Linux operating system and the I2B2 [13] framework upon an ORACLE® database for the storage were selected and installed as the core CDW infrastructure.

The first security principle we applied was the anonymization of all data identifying patients, both for structured data or for non structured data (free text reports). In some cases, it is nec-

essary to restitute patient identifiers, so anonymization has to be reversible. All non identifying data (biological results, physician order entries, ICD-10 codes, etc.) are available without restriction. Patient-identifying data are encrypted with a strong reversible cryptographic procedure based on a AES algorithm implemented using the Bouncy Castle java libraries [14]. For experimentation, we are using a 128 bit-long AES key. This encryption function has been integrated into the jobs used for data migration that also use the java language.

For structured data, HIS patient identifiers and hospital stay identifiers are also eligible to anonymization. These two identifiers are used in the CDW as primary keys in the database tables and the encrypted identifiers are bigger (in terms of internal machine representation) than the non-encrypted identifiers. We therefore modified the storage format of some I2B2 tables in the ORACLE® database. We modified the I2B2 client accordingly to manage the new format of patient identifiers.

For non structured data sources (e.g., text reports from in/outpatient stays or surgical interventions), anonymization involves five successive steps:

1. Extraction of Microsoft® WORD-based text reports from the EHR database: a first PHP script using MS ActiveX objects extracts and uncompresses the native WORD-based text reports stored in the DxCare®/Medasys EHR database.
2. Conversion from WORD format into DocBook XML format with the ANTIWORD program.
3. Tagging of identifying data: a NLP tool is used to mark identifying data inside DocBook XML-based reports with new tags.
4. Encrypting of tagged data: the AES algorithm is used to encrypt reversibly tagged data inside XML-based reports with the 128-bit AES key.
5. Integration of encrypted XML-based reports in the CDW database with a second PHP script.

The data realm

As the first milestones of security and data protection were established, we assessed integrating real patient data into the CDW. Data realm implementation consists of three steps.

Step 1 – Identification of data sources

This step requires knowledge and expertise from legacy data sources necessitating close collaboration with the various application vendors.

Step 2 – Mapping of data sources into the target schema

The target schema is the five-axis star schema of I2B2 (PATIENT, PROVIDER, VISIT, CONCEPT and OBSERVATION) [13]. PATIENT, PROVIDER and VISIT related data are easily extracted from the data sources and mapped to the target schema because our CIS components already structure their data according to these axes and the corresponding items can be almost directly integrated into the I2B2 schema.

CONCEPT mapping

The attributes of the data source related to the CONCEPT axis address the issue of the classifications and terminologies used; these are very intimately linked to the business logic with which the data are created. In the I2B2 framework, each classification or terminology must be transformed into a tree structure (i.e. a hierarchy with single inheritance links). Therefore, the initial phase of CONCEPT mapping consists in providing:

1. A name for the new classification used by the data source;
2. A SQL request (r1) that returns a raw dataset including 1) the names of concepts in the new classification; 2) the identifiers for the concepts; 3) the identifiers of the parents for each concept.

Then, each line returned by (r1) must be transformed into I2B2 storage format with the tree structure constraint: the location in the classification is managed by a text field that is calculated as the sequence of the traversed levels from the root of the hierarchy down to the associated CONCEPT. This step can be performed by a second SQL request (r2).

OBSERVATION mapping

The attributes of the source data related to the OBSERVATION axis are the primary data subject to computation and analysis in the CDW. The initial phase of the OBSERVATION mapping is to provide a SQL request (r3) that extracts raw dated facts which comply with the four following constraints:

1. They must be related to a (single) patient.
2. They must be temporally dated: data that are not dated (for example the first name and the last name of a patient) are theoretically not eligible to be stored in the OBSERVATION axis.
3. They must be "generated" within the scope of the healthcare process, with an identified creator or source (the PROVIDER) and with an identified medical event (the VISIT), for example a consultation or a hospitalization.
4. They must be associated with a concept (an anchor in a classification loaded in the CONCEPT mapping step).

Then, as in the case of CONCEPT mapping, each line returned by (r3) must be transformed to meet I2B2 table format constraints (r4).

For each new DATA SOURCE, we have implemented these four different requests with dedicated ORACLE views using copies of the CIS databases (Figure 1). Copies are managed with ORACLE® import/export utilities to prevent direct use of production databases. The views are used in the Open Source Talend® ETL jobs when data are migrated. A master job encapsulates all ETL jobs to provide a single access point for integrating all CDW data at once.

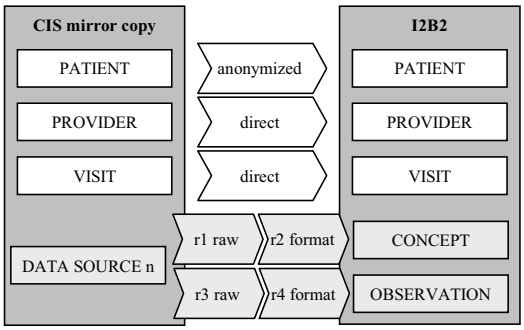

Figure 1 – Overall synopsis of data mapping

Step 3 - Building of dedicated datamarts

An important issue is the availability of data at the relevant level of granularity [15]. In the CDW, data are stored at the lowest possible level of granularity (as observation facts) and this may not be appropriate for users who want highly aggregated data. Hence, when necessary, dedicated datamarts are created for storing aggregated data at a required level with ORACLE materialized views. These materialized views allow specific design and fast access to pre-computed variables.

As concerns the PATIENT, PROVIDER and VISIT axes, the I2B2 database is loaded with 1,214,000 patients, 1,058,000 stays and 975 hospital units stays (as of September 2009); for the CONCEPT and OBSERVATION axes, we have integrated seven main different data sources into the CDW (Table 2).

Table 2 - Data sources currently integrated into the HEGP CDW (September 2009)

Data sources	Number of concepts	Number of observations
Laboratory results	7,291	62,819,471
Drug prescriptions	31,363	1,002,940
Clinical observations from structured forms	5,224	20,842,494
ICD-10 codes	21,356	1,874,639
Medical act codes	10,050	1,775,283
Consultation and hospitalization text reports from the cardiovascular department	39	165,873
DRG codes	3,771	467,281
TOTAL	79,094	88,947,981

The restitution realm

The restitution real analysis involves user interaction and functional integration with other CIS components. The main objective of the CDW is to facilitate access to clinical data for users and these users may have different profiles [12]. We therefore used dedicated tools for each user profile:

- Power users: SchemaSpy (to navigate in database models) and DocuWiki (to maintain technical documentation)
- Standard and occasional users: SAP/Business Objects (to design reports) and KaliTech®/Kalidoc (to integrate reports into the enterprise content management system)
- Searchers: I2B2 dedicated client

The restitution of CDW objects was evaluated through various pilot studies including:

1. EHCR quality management (clinical report exhaustivity for the year 2008)
2. Evaluation of medical prescription practices by studying simultaneous biological prescriptions of ESR and CRP in the hospital (since the year 2003)
3. Evaluation of a rule-based engine dedicated to pharmaceutical validation of drug prescriptions [16].

The administration realm

For the Administration realm, we decided to enlarge the functional perimeter of the Help Desk used in the hospital (Peregrine software®/GPS) to cover CDW functionalities such as "Request for new dashboards". For the two pilot domains, we used the Peregrine®/GPS software to register dashboard creation, and thereby monitor the evolution of these two CDW objects in the future.

Discussion and conclusion

CDW can be used in the health sector with several objectives, including: 1) quality management (for auditing or for outcome studies); 2) identification of best practices; 3) population follow-up (for predictive medicine or disease registries); 4) clinical investigations or case studies; and 5) intervention studies (as in before/after studies or controlled trials). The success of the CDW depends on the preexistence of the CIS producing and storing raw clinical data. The two components evolve in synergy: the CIS is the main source of data for the CDW and the CDW produces data (indicators, reports) that enhance the overall healthcare activity, which is in turn processed by the CIS.

In this paper, we have presented the methodology used for integrating a CDW based on the I2B2 framework into the information system of the Georges Pompidou University Hospital. We were able to initiate a global methodology for integrating heterogeneous databases into an open, community-based framework that allows integration with other HIS components for data restitution.

The open source feature of this framework helps with the adaptation of the core database model to implement our security strategy based on a strong reversible encryption algorithm applied to all patient-identifying data.

The simplicity of the I2B2 star schema model facilitates several tasks:

- Creating generic procedures (either with ORACLE® views or with Talend®/Open Studio jobs) for data integration into the CDW. In the data mapping step (figure 1), View 2 and View 4 are generic, and this accelerates new data source integration.
- Creating dedicated datamarts with ORACLE® materialized views to allow both the design of oriented analysis of new aggregated variables and to accelerate their computation and their integration into users' reports.
- Designing a dedicated SAP®/Business Objects universe layer for building reports and dashboards with raw or aggregated, CDW data.

We have also initiated the use of the Peregrine®/GPS helpdesk system but only in the scope of pilot domains. A specific task of user training is required to encourage the use of this help-desk software in the context of the hospital CDW.

We will continue to deploy a procedure to update the CDW data continuously from the currently integrated data sources, to add new data sources such the hospital bio-bank, and to evaluate the benefits and drawbacks of the CDW in a production environment. An important issue is the usefulness of the CDW for routine selection of candidate patients for clinical research studies. Another is the value of the system for feeding CDISC electronic case report forms (e-CRF), partly or completely, with data stored in the CDW to evaluate research fostering strategies such as those described in [17].

Abstract

Pervasive Development Disorders (PDD) represent a life disorder which significantly affects individuals and families. It requires long term specialized institutions health care, education and social accompaniment. In France, 350,000 to 600,000 patients are estimated to be affected and 5,000 to 8,000 newborns will develop the disorder every year. In 2005, Autism Resource Centres were created in each of the 23 regions in France, to support the PDD hospital reference centres in providing formal clinical assessment for each patient. Such assessments will support the prescription of health care measures, educative and intuitional orientation and accompaniment. An information system called TEDIS was designed to assist the psychiatrists and multidisciplinary medical experts at Necker child-psychiatry hospital, in organizing PDD patients' information and providing ground for improving knowledge about the disorder, its epidemiology and underlying biological mechanisms. The professionals' involvement from the beginning in the development process facilitated TEDIS design and implementation. The results of first experimentations are encouraging. They are described as well as the short term and mid-term deployment planning.

Keyword :

Autism, Pervasive Development Disorder, Information system, Internet, Dynamic web server.

Introduction

The concept of autism was extended since its first description by Kanner in 1943 to Pervasive Developmental Disorder (PDD)*. This latter represents a broad range of disorders characterized by the association of difficulties to communicate (verbal and non verbal communication), impaired social interaction and restricted, repetitive and stereotypes of behaviour patterns (DSM-IV, American Psychiatric Association, 1994 [1]). PDD may be associated or not to a mental delay. The frequent association with other neurological and organic disorders such as Bourneville Tuberous Sclerosis suggests a multifactorial aetiology of PDD.

Estimates of the prevalence of autism and PDD are moving towards increase in rates [2]. Recent studies have consistently provided PDD estimates in the range of 60-70/10,000 being thus one of the most frequent childhood neurodevelopment disorders [3]. In France, 350,000 to 600,000 patients are estimated to present with PDD and 5,000 to 8,000 new-borns will develop the disorder [4].

Diagnosis is based upon a precise behavioural and communication analysis of children about three years old. The treatment consists of life term care: a series of early and individually adapted measures in the domains of education, behaviour and psychology. Treatment compliance, may significantly improve the relational capabilities and social interaction with some degree of autonomy and possibility of language acquisition and non verbal communication.

Therapy costs are not negligible in the PDD context. Comparative direct health care costs studies between children affected with PDD, asthma and diabetes, showed the costs for PDD were two- to threefold higher than for asthma and diabetes ($4,815 vs. $1,469 vs. $2,404 respectively [5]).

PDD represents an important issue in public health as an increasing number of families and individuals seek educational, social and health care services to deal with the large impact of the affection [4, 6]. In France, public health authorities supported, particularly since March 2005, the creation and development of National and regional "Autism Resource Centres"†. They involve a multi-disciplinary team of experts in autism, who collaborate in favour of early PDD diagnosis, promoting research, assistance and providing information, counselling and expertise to the patient' families and to the health care and social professionals [7]. The Autism Resource Centre of the region of Ile-de-France region (11,616,500 inhabitants) coordinates five medical departments to provide clinical assessment expertise in patients affected with PDD.

The department of pedo-psychiatry (child-psychiatry) at Necker Hospital in Paris is among them. It beneficiates from two care units for autism assessment: an outpatient unit where PDD patients are hospitalized for a 3 weeks period and an ambulatory unit where patients are hospitalized during 4 days for checkups. The majority of children evaluated are between 3

* In french : Trouble Envahissant du Développement – (TED)

† In french : Centre de Ressources Autisme - (CRA)

and 6 years old. They undergo evaluation in a variety of domains: clinical assessment of psychological, motor and speech development, consultation in neurology and genetics, as well as specialized para-clinical exams including brain MRI with spectroscopy, contextual EEG, standard and high resolution caryotype, searches for chromosomes alterations by fluorescence in situ hybridization (FISH) and for metabolic disorders. Additional investigations guided by the clinical exam are prescribed as necessary.

A written report is issued at the end of the assessment. It is transmitted to the parents, to the care providers and/or to the institutions involved in the patient care. Formal demands are consequently addressed to specialized institutions to consider patient admission, to the Institution of Handicapped Persons [‡] (MDPH) to qualify the handicap and to the Social Security medical officer to qualify the long term character of the disease [§] (ALD) in order to beneficiate from the medical care cost coverage. For the last five years, about 250 children between 3 and 6 years old who consulted in the Necker child-psychiatry department were diagnosed as affected with PDD. They underwent an exhaustive clinical and para-clinical evaluation. The initial paper-based screening, despite its exhaustivity, contributed to find an aetiology in only 5% of the patients. Besides, it was not adapted to support complementary epidemiological and aetiological researches.

The need for a database system to automatically process patient's clinical information and support the multidisciplinary efforts in characterizing PDD was raised. The database system will focus on prospective patient assessment data in child-psychiatry department and integrates conclusions from genetics, neurology, ophthalmology, ORL, radiology, biochemistry departments. Longitudinal follow-up of PDD patients, will help evaluating the clinical evolution and adjusting prescription of medical, educative and social therapies. The database system will allow evaluating the significance of correlation between PDD phenotypes and genetic and/or biological disorder, and support further research studies. An information system called TEDIS (Troubles Envahissants du Développement – Information System) was designed based on formal cognitive engineering sessions between experts in the child-psychiatry department at Necker Hospital and in Biostatistics and Medical Informatics Department in the same hospital.

In the next sections, we will first present the objective and functional specifications of TEDIS and the database conceptual data model. We will then expose the present experimentation and planned project actions in the short term and the mid-term.

Material and Methods

Related works

Few databases related to autism are found in the literature; none in France dealing with experts' PDD assessment.

Database content: autism

- Daslne [8]: is a database of children with autism spectrum disorder living in north east of England was established in 2003 on a standalone computer in Newcastle University.
- AutDB [9] aims at providing current knowledge on candidate genes linked to Autism Spectrum Disorder. The content of AutDB originates entirely from published scientific literature and is manually annotated by expert biologists.

Production database within a Decision Support System

From the beginning TEDIS was designed to integrate a production database documented by end-users (clinicians) and controlled by psychiatrists into a decision support system. This latter will interact with additional automated internal and external resources, and will support health care decision making, epidemiology and research. There are several such systems in the medical literature. We will remind two of them developed at the Biostatistics and Medical Informatics in Necker Hospital for the proximity of the challenge, the data modelling and system implementation.

- MSIS Multi-Source Information System [10, 11] dedicated to patients with end-stage renal disease. Built on n-tiers architecture, dynamic web-server, with a patient identification server, a production database, a data warehouse and geographic information system.
- CEMARA [12]: covers a broad variety of rare diseases. Built on shared rare-disease data subset and on specific disease data sets.

Knowledge engineering meetings

Twice a month since October 2008, knowledge engineering meeting sessions gather senior and junior medical experts with the knowledge engineer to elicit the PDD' domain information specifications and users application requests.

TEDIS' application interface template was used to organize and represent the PDD domain information. It served as a mediator and supported feedback exchanges with the professionals between engineering sessions. Specific information subsets were validated progressively this way.

TEDIS' Objectives and functional specifications:

Objectives

- Improve PDD patient's health care, educative measures, social counselling and recommendations and support multidisciplinary collaboration;
- Contribute to a better knowledge of the aetiology and epidemiology and support heath care decisions, health care research;
- Contribute to improve systematic PDD patient's data collection in the reference centres, extend the use of the system and promote collaborative national and international research, with the respect of patient data privacy and interoperability standards.

[‡] In french : Maison des Personnes Handicapée (MDPH)
[§] In french : Affection de Longue Durée (ALD)

Database general specifications

The database has to be remotely accessible through secure connection, highly available with rapid response time. It should allow multiple and simultaneous accesses and support transactions. It should be scalable to accept growing data load from additional child-psychiatry reference centres.

TEDIS patient data privacy will be guaranteed through logical and physical processes complying with the national commission of freedom and computing (CNIL) recommendations.

The conceptual data model

Patient database

Nominative patient data are stored in a separate database. This design facilitates managing sensitive information and allows rapid searches for potential duplicates in patient data entries [13]. A sequential unique patient identification number is generated and serves to relate records from multiple database tables to a single patient file. Additional variable keys characterize individual clinical events such as: initial PDD state, expert assessment, multidisciplinary medical experts' decision at first visit / follow-up observation assessment.

Functional specifications

Clinical data: temporal assessment events:

- Initial state: It is a dated event corresponding to the first time the PDD diagnosis was assigned to a patient. It can be anterior to or the same as the first visit date to the child-psychiatry expert centre at Necker hospital. There is one initial state observation per PDD patient file. It includes:
  - Personal and family medical history, with psycho-social environment and context;
  - Pregnancy medical events and the parents' psycho-sociological assessment;
  - Birth reports;
  - 0-3 years period with developmental data concerning motor skills and language acquisition, context of schooling, social environment, major medical events;
  - Patient care, therapeutics, educative and social measures, before formal expert PDD assessment.
- First visit / Follows-up visits: these are also dated events, with a reference date of PDD' assessment in the child-psychiatry department. Follow-up assessments occur after a period of 18 months since last expert assessment. They include information about:
  - Context of visit to the department of child-psychiatry, the description of the objectives, the settings and the context of the patient evaluation;
  - Psychopathology assessment with specific detailed clinical tests of psychological, clinical, speech and motor assessment. For each assessment, a developmental age in comparison with the chronological age is assigned by the clinical expert;
  - Multidisciplinary assessments include: paediatrics, genetics, neurology, hearing and visual consultation and investigations, detailed electro-encephalogram characteristics, cerebral MRI results.
  - Based on the clinical assessment in the child-psychiatry department and in the multidisciplinary team, measures are proposed for school and educative orientations as well as re-educative and therapeutics treatments, in outpatient clinics or in full time care institution. A main medical diagnosis, based on ICD10 codification qualifies the patient disease. It may be documented with three associated medical diagnoses.
  - Multidisciplinary medical expert's staff decision may adjust or confirm the diagnosis or suggest further investigations. The patient case may eventually be included in a research protocol.

Data model

TEDIS relational data model, presented in Figure 1, is organized on individual PDD patient identification file.

The related medical information are stored in separate databases and linked to the patient identification using the patient identification number.

The data model matches the PDD patient organization.

An initial clinical state observation, before expert' assessment, is attached to each patient file.

A dated observation corresponding either to the first visit in the child-psychiatry department or to a follow-up visit (we will refer to both kind of visit as follow-up visit) is affected to the patient file. Follow up visit records are affiliated to the patient file.

To each follow-up observation, dated medical conclusions from experts in other disciplines are attached as well as dated observations of therapy measures and multidisciplinary staff recommendations.

The chronological sequence of observations may be described this way:

A patient identification record is created. An initial state observation, with a reference date: the date of the first time PDD diagnosis is attached to the patient file. An actual (follow-up) assessment observation enhanced with multidisciplinary assessment observations and therapy recommendations are attached to the patient file. Periodic clinical assessments are documented and attached to the patient file. Longitudinal information for a PDD patient cohort may be generated this way.

Additional information related to TEDIS' user profile, medical centres and medical thesauri, administrative data, standard list of professions, geographic locations, are organized in separate databases and used to document each patient record.

Finally, the database system is designed to easily accept PDD patient assessments from additional PDD reference centres.

Dynamic Web server

We implemented TEDIS based on n-tier architecture and thin Internet client through a secured web-interface connection. We used the Java JSP/Servlets technology and the Apache Tomcat Web server to communicate between the client and the MySQL database server. The servers are deployed on Linux environment [14] in tested secure architecture.

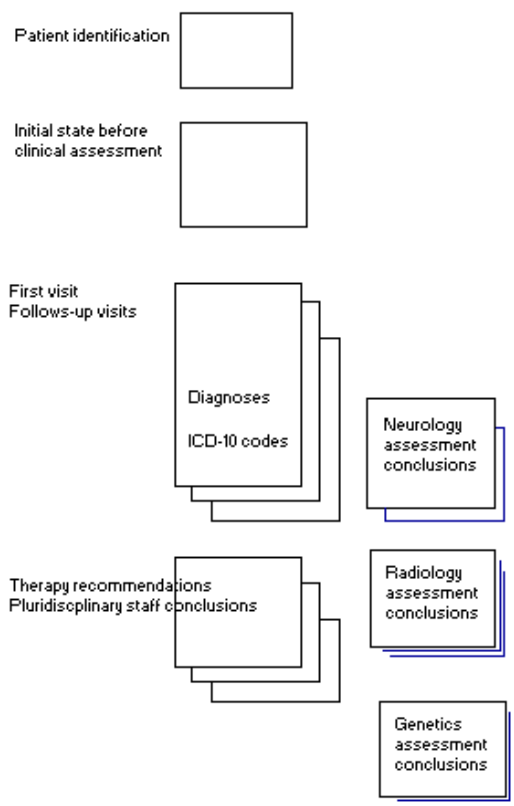

Figure 1 – TEDIS data model: To each patient record are affiliated: an initial state before assessment observation, one or many follow-up visit observation, one or many multidisciplinary assessment observations and one or many multidisciplinary staff therapy recommendations.

Experimentation

The experimentation is organized into phases:

- Current phase consists of testing the paper template forms issued from the TEDIS application interface, to assess its acceptance among a variety of professionals, the easiness of its use, and its completeness according to TEDIS objectives. The impact of data availability for entering retrospective and prospective patient records were evaluated as well as the need of a medical expert to fill or supervise filling which subsets of PDD patient information.
- The application will be deployed current year and the objective is to enter by the end of this year all 2009' PDD expert assessment observations about 50 patient records.
- Besides continuing collecting prospective data in 2010, retrospective patient's observations, about 250 observations, will progressively be entered in the system.
- The deployment and user training will continue in the following period. The ability of TEDIS to support the multidisciplinary staff meetings, based on the data collected will be tested during this period.
- During 2010, major TEDIS functionalities built around the production database and the TEDIS application are supposed to be stabilized and to be able to accept patient's data from additional PDD reference centres.

Results

Actually a minimal patient record of PDD' patients assessment in child-psychiatry and related medical disciplines was made available as the result of collaboration between medical informatics and medical domain experts. It is agreed upon among a large community of health professionals including psychiatrists, psychologists, speech therapists, neurologists, radiologists, geneticists, etc.

According to the professionals among psychiatrists and psychologists who tested the paper forms issued from TEDIS: the application form interface is structured in a way to allow fluid move from specific assessment subsection to a general overview representation of the multidisciplinary assessment. TEDIS forms are easy to fill.

Twenty PDDS' patient records were filled by medical expert of child-psychiatry. This experiment pointed out the difficulty to fill retrospectively patient records because of unavailability of information and the need to make specific searches. It was time consuming and required about 20minutes completing retrospectively a PDD patient record.

A second observation from this experiment concerned the need of a medical expert to fill most of the clinical assessment sections as they required specific test results qualification and integration. Administrative data and event dates such as multidisciplinary assessments dates and clinical authors may be completed by non medical staff members.

Discussion

Existing PDD database systems are either too specific in comparison with TEDIS' focus (e.g. evolving medical expert assessment) or complementary in the domain of autism and PDD. In contrast with existing database systems, where patient associations primarily influenced the database design [8],

TEDIS was designed with medical experts in child psychiatry, to respond to their demand to organize growing patient's data.

TEDIS is dedicated to PDD patient expert assessments for a better knowledge of the demand of care and for adapting and coordinating the multiple care issues and resources. The accumulation of quality data of prevalent and incidents patients will provide valuable resources for assessing early diagnosis, enhancing therapy measures, developing epidemiological analyses and supporting research in particular in relating genetics and biological processes to clinical phenotypes of PDD.

The design of TEDIS' database system opened to extend data input from multiple child-psychiatry medical centres, offers the perspective of improving systematic PDD patient's data collection in the reference centres and promoting collaborative work between child-psychiatry centres as well as international research, respecting patients' data privacy and interoperability standards.

Challenges of interoperability, epidemiology data analysis and researches in genetics and biology correlations will characterize future developments of TEDIS.

Conclusion

Modelling medical domains remains a challenging and a continuing task. It has to fit with the health care community needs for a better knowledge of the care demand and for a better planning of the offer of care. Implementation of the data model has to support the professionals' patient data management in daily use and favour collaborative multidisciplinary team work. Integration into a decision system will support research and enhance decision making.

The data collection process has to be opened and favour collaborative work between domain expert teams and decision makers. It has to profit from advances in technologies and rely on interoperability standards. TEDIS is dedicated to patients with PDD, was designed to meet with these challenges.

Acknowledgments

Medical experts and health professionals particularly at the Child-Psychiatry Department at NECKER Hospital are warmly thanked for their support and feedback, as well as Mr J.P. Necker at Biostatistics and Medical Informatics Department.

Developing a User-centered Voluntary Medical Incident Reporting System

Lei Hua, Yang Gong

Department of Health Management and Informatics, School of Medicine, University of Missouri, USA
MU Informatics Institute, University of Missouri, USA

Abstract

Medical errors are one of leading causes of death among adults in the United States[1]. According to the Institute of Medicine, reporting of medical incidents could be a cornerstone to learn from errors and to improve patient safety, if incident data are collected in a properly structured format which is useful for the detection of patterns, discovery of underlying factors, and generation of solutions. Globally, a number of medical incident reporting systems were deployed for collecting observable incident data in care delivery organizations (CDO) over the past several years. However, few researches delved into design of user-centered reporting system for improving completeness and accuracy of medical incident collection, let alone design models created for other institutes to follow. In this paper, we introduce the problems identified in a current using voluntary reporting system and our effort is being made towards complete, accurate and useful user-centered new reporting system through a usability engineering process

Keywords:

Patient Safety, Incident Reporting, Usability, Task analysis, heuristic evaluation

Introduction

The University of Missouri Health System has implemented a web-based medical incident reporting system called Patient Safety Network (PSN) since 2002. In the previous study [2] on one year dataset of medical incidents, 2,919 cases out of total 5,654 reports were finally extracted as non-duplicated and valid data after cross checking consistency and completeness. Among them, 958 cases (32.8%) were labeled with "miscellaneous", which was too blurry to be analyzed in-depth even after laborious manual data pre-processing. In addition, the rest of dataset still face challenges due to chunks of descriptive incident data in free text format.

The completeness and accuracy of reported incidents are core attributes for meaningful use and iterative improvement of voluntary medical incident reporting system. According to the previous researches, plenty of conceptual blurs were existed in the process of medical incident reporting. For example, how to break down the "miscellaneous" dataset into distinct subclass; how to build a comprehensive hierarchy to precisely express incident classes such as "fall", "medication/IVs"; how to approach a rating scale system of harm score for reporter to evaluate incident severity with less uncertainty; and how to improve reporting process for meaningful description of medical incidents. These are the questions asking for higher quality of data entry. On the other hand, system utilityb[3] perceived by levels of users could either accelerate or impede the enhancement of such application, which depends on system feedback. For instance, the comprehensive summary and analysis results of incident data generated by system is a foundation to develop collaboration for system using among the stakeholders such as reporters, analyzers (designer) and CDO leadership. That feedback cycle could effectively and efficiently assist designers in interpreting and working out the problems that arise during use, and in return, different level of users can quickly perceive improvement in person. Consequently, a sustained development process of user-centered voluntary medical incident reporting system could be established. However, all supposed achievements above heavily rely on quality data.

For this purpose, we are redesigning a voluntary medical incident reporting system with user-centered concerns. In contrast, the current PSN system has a variety of usability weakness and heuristic violations in aspects of site structure, navigation, scanability and flexibility, according to Nielsen's guide book[4] for web design. Therefore, usability is regarded as a standing point of user-centered reporting system design at the initial stage of our study.

Previously, usability was proved as one of most influential human factorsb[5] to usefulness and ease of use in this kind of system. From recent published literatures [6-7], it comes to the fore that the ultimate accept or reject of such system largely relies on the degree of system usability [8]. By far, due to time pressure and immature theories of engineering method, the usability studies were rarely conducted in the process of existed medical incident reporting system design and development system. However, it is believed that the usability issues are included from the beginning of the development process not only the iterative design cycle may shorten, more importantly new insights might be acquired on general system design aspects that might potentially lead to errors in healthcare. So in the entire project, we combine usability engineering as an initial part of development cycle for a user-centered medical incident reporting system.

Methods

The user-centered design framework [9] requires analysis at the user, task, function and representation level for effective design and evaluation of an information system. In a prototyping process, we started with a dominant type of users (nurse)

and employed a horizontal dimension prototyping method [3] to keep the features yet eliminate the depth of functionality.

Focusing on the functionality of reporting, firstly we conducted a task analysis inspecting the PSN interface to measure several fixed factors that might influence usage of system and set a series of goals for improving identified weakness. Secondly, we developed a new web-based interface using JavaScript, PHP and ExtJS library with new features on technology and content management such as Ajax and procedure based question-answer. And then executing task analysis again on the new interface aimed to confirm achievements of new design. Meanwhile, we conducted a heuristic evaluation to identify severe usability violations and use the results to improve the overall user-friendliness.

Task analysis

Referring to Nielsen's book of usability engineering [3], a task analysis is to study how users approach the task, their information requirements and how they deal with exceptional circumstance, identify points where users fail to achieve goals, spend excessive time, or feel uncomfortable. The analysis generates a list of all the information users will need to achieve goals, the steps that need to be performed and the criteria used to determine the quality and acceptance of results. In this case, we set three variables as inspected objects: mouse click, key stroke and memory load. By emulating a typical user's operation in reporting a patient fall incident, the step counting on these three aspects were summarized and grouped into four sections: initial questions, event common questions, event details and summary & others, as it shown in Table 1. The improvement of system on such concerns is believed to visibly reduce the operational and mnemonic workload in the process of incident reporting. What make these three factors interest us is they can be measurable and improvable by interface re-engineering.

Concretely, we went through the PSN and new interface with the same scenario of patient fall, which requires largest number of questions in all existed eight types of event. They are including blood/blood products, skin impairment, medication reaction, equipment/device, medication/IVs, fall, procedure/treatment and miscellaneous. The number of mouse click and free text input was calculated and summarized for same steps of each interface. Simultaneously, the analysis of memory requirements was conducted for each section (a granularity defined above) of two designs to measure memory requirements of reporting system questions. In the end, all summarized outcomes on mouse click, key stroke and memory load were listed into a tabular format for comparing differences of two systems. This spreadsheet can intuitively illustrate the progress in usability issues between the two interfaces.

Heuristic Evaluation

Heuristic evaluation is a usability inspection method effective in uncovering design problems, which is considered to yield the most serious problems with the least amount of effort [10]. For this discount evaluation method, 3-5 usability experts are recruited to inspect interface design problems, and then they are requested to summarize and report heuristic violations as a basis for usability improving.

For resource limitations in terms of time and finance, we eventually enrolled three doctoral students majored in computer science with proper training on heuristic evaluation method. They were asked to use the 14 usability heuristics developed by Zhang et al. [11]. The 14 categories refer to: Consistency; Visibility; Match; Minimalist; Memory; Feedback; Flexibility; Message; Error; Closure; Undo; Language; Control; Document.

Table 1-The requirements at the Key Stroke, Mouse Click and Memory Load level of two interfaces

Sec	Task		PSN(A) Prototype(B) Both(S)	Key stroke	Click	Memory Load
Answer Initial Questions	Anonymous Report	A	RadioGroup check(Y/N)		1	Recall the title of health profession, facilities where incidents occurred and level of patient involvement
		B	Checkbox(default:uncheck)		0~1	
	Health Profession	A	Pulldown list		2	
		B	Has default value, auto-complete entry	Initial letters	0/2	
	Involvement	S	RadioGroup for facility and patient involvement		2	
Event Common Questions	Demographic	S	Name,Birthday and Gender	Patient name entry	10~11	Patient ID or name; When the incident happened and what date is that day; patient home unit and related doctors
	Event Date	A	Time pickup widge		2~3	
		B	Add with default value, two shortcut buttons		0~3	
	Address & clincians	A	pulldown list,text field		7	
		B	Add with auto-complete	Initial letters	7	
Event Details	Type & Harm Score	S	Both are RadioGroup check widgets		2	Recall entire process of incident and compare them with page quesitons in mind, then make a precise or
	A series of questions to depict cases,e.g."fall"	A	Single & Multiple textfields, RadioGroup, Checkbox, Dropdown list	up to 6,000 free text input	6+	
		B	Procedure based question-answering radio groups	Specify in short for unlisted items	4~11+	
Summary Other	Review info; save,submit, delete	A	Review but cannot modify info		1	memorize which question and which page this question is in
		B	Can modify most of info		1	
	Page flips	A	Button for backing to previous page		9	
		B	Navigational bar takes page flips		9	
Total		A		very much	42~44+	
		B		a few	35~49+	

Three experts were asked to conduct an on-site evaluation as a group. The entire process took about 60 minutes. The first 15 minutes were spent to explain background of evaluation, hand out an evaluation stepwise description and make a brief demonstration of interface operating. Then the experts did the evaluation as a group but individually, due to the timely evaluation for the first version of prototype. One of them played the interface as an incident reporter according to stepwise task description. At the meantime, the rest observed operations and inspected system features and feedbacks. They were asked to go through the interface together several times with following 14 usability principles (14 usability heuristics) and developed pertinent discussions. The group of evaluators jotted down usability violations and solutions suggested, and then rated a severity score for each usability violation based on the following scale:

- 0 - Not a usability problem at all;
- 1 - Cosmetic problem, need not be fixed unless extra time is available on the project;
- 2 - Minor usability problem, low priority to fix;
- 3 - Major usability problem, important to fix, so should be given high priority; and
- 4 - Usability catastrophe, imperative to fix before product can be released.

In the end, such results organized in Excel format were sent back to us as a feedback. The entire process was audio-taped and later reviewed several times to find out missing parts and remove duplicates (same meaning in different expressions). All of our modifications were emailed back to each evaluator for verification purposes.

Results

As a result of task analysis, Table 1 exhibits the detailed combination of two analyses. It manifests the interface testing outcomes in terms of mouse click, keyboard stroke and the retrieval of mnemonic information. The four sections of tasks were investigated, including initial questions, event common questions, event details and summary/other. The number of mouse clicks varys, which depends on if default value applies or not (e.g. 0/2 means that selecting "Health Profession" require 0 or 2 mouse clicks) and if a question has multiple values (e.g. 4~11+ means that depicting a fall event requires 4 to 11 plus mouse clicks to answer questions in format of radio button and checkbox). The column of key stroke argues the reasons of text inputting for each interface. And the last column elaborates the requirements of mnemonic data to each section. In total, the new design has a large range of mouse click counting number, 35~49+ clicks based upon a typical case used for testing; whereas, the PSN has 42~44+ clicks. But for requirements of key stroke and memory load, the new design requires much lower.

The changes above came with the following technical progresses we made in the new interface.

- Set default values with statistical evidences. E.g. our analysis shows nearly 70% of reporters are residential nurse and nearly70% medical incidents were reported within two days after occurrence. Therefore, setting "RN" as default value and creating two shortcut buttons for picking up today's date and yesterday can facilitate data entering.
- Present accurate and meaningful prompts at the appropriate position. E.g. replace a chunk of static instructions with over-the-cursor button tips and show concrete date on today's date button
- Shortcuts for data entry and adjustment. E.g. easy page flips, can edit almost all entered data at summary page
- Using closed-ended questions to substitute open-ended ones.
- Procedure based ("if-then" rules) process combined with closed-ended questions for collecting event details. Using standardized multiple choice questions to substitute open-ended questions in formats of multi-lines text field, single-line text field, checkbox, etc.

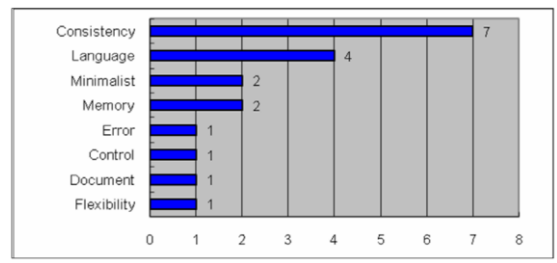

Figure 1-The categorical distribution of identified 19 usability violations

By heuristic evaluation, 19 usability violations were identified, which belong to 8 heuristic categories. Consistency and Language were the two heuristics most frequently violated in the new user interface. These two categories alone accounted for nearly 60% (11/19) of all the identified usability violations. The specific distribution of heuristics violated in this step is presented in Figure 1.

The concrete descriptions of result were organized into a tabular spreadsheet, which is a list of 19 usability problems found through the interface as well as hints for features to support successful user strategies. There are total six sections, including five sections of date reporting (initial info, event common info, event details, summary and harm score), as well as one section for general problems. The severity scores rated by three evaluators are averaged and the narrative texts are reorganized into proper categories. The Table 2 is an excerpt from all identified violations with severity score over 2.5 (major and catastrophic violations). In this table, the sections are consistent with them in Table 1.

Discussion

This study demonstrated the initial employed strategy for usability engineering a voluntary medical incident reporting system. First of all, the two dimensions of prototyping methods were introduced to decompose the entire system development into vertical and horizontal levels. Then, at the vertical level, we did research on reporting functionality of the current PSN and new interface to discover variables influencing usage of system through task analysis.

Table 2-An excerpt from major and catastrophic usability violations

Sec.		Problem Ddescription (P) Recommended Solution (S)	Heuristics Violations	Severity Rating
Initial Questions	P	No explanation to red asterisks for required questions	Document	4
	S	Explain at the first place where red asterisks appeared		
	P	Layout of two radio group widgets	Consistency	2.66
	S	Indent the options of these two widgets, use shaded block to highlight them		
Event Details	P	The name of button which triggers a reset of start over the event details question	Language	3
	S	Change button text ""restart"" changes into ""reload this page"" or ""clear""		
	P	Use "check one" to be a alert for radio group that only can check one option	Minimalist	3
	S	Remove "check one"		
	P	User is maypossible to forget to rate for event harm score	Consistency	3
	S	A better reminder or put it event harm score section into one a separate page to instead of on the navigational bar		

And at the horizontal level, we started a heuristic evaluation on the new interface with improved factors mentioned above. Such an iterative analysis, development and evaluation process will be continuing until all issues such as user types, tasks, functionality and data representation are completed at the both vertical and horizontal levels. This is our usability engineering method for system prototyping.

There are two reasons for us to follow the PSN system and develop the new system framework and data entry process. One is because some of changes made to solve certain problems may cause new problems. Another reason is about learnability. A substantial modification could make system new to current users and break down their previous convention and understanding of reporting a medical incident. The relearning could cause frustration to expert users and be time consuming for both novice and expert users.

In task analysis, three factors were identified to largely affect users' performance of reporting. They are memory load, key stroke and mouse click. Comparing the two analysis results on existing and new incident reporting, the memory requirements of new one for manipulating interface and incident recalling were decreased largely. An impressive enhancement achieved is for answering event details. In the PSN system, it used many different widgets for such data collection including 2 single text fields, 2 multiple text fields, 4 pull-down lists, 10 radio/checkbox groups and 7 buttons. All of them laid out in a two screen high (screen resolution is 640x480 pixels) page. The users have to scroll the page back and forth and leap blindly among the confusing questions which are considered heavy burdens of memory load per cognitive theories. Furthermore, those two multiple text fields allowing up to 6,000 characters free text input can frustrate reporters and results in various levels of details of reporting. On the contrary, the counterpart of new design followed the Common Formats of AHRQ and set up less than 11 causal related questions in closed-ended format meeting the same goal. Such improvements not only lower the memory burden, but also can remarkably decrease the number of key strokes. On the other hand, though the number of mouse clicks is still as similar as it before, the actions of clicking became easier and less clicks could be achieved once reporter is a default user. For instance, a nurse reports an intraday incident. Obviously, the conciseness and easiness achieved by new interface is able to enhance reporting efficiency and users' satisfaction.

There is a trade-off we have to address. To avoid catastrophic errors may lead to design a less efficient user interface, such as adding extra questions to assure the user is certain about a particular answer or action. And adding auto-complete function to pull down list can save the time and lower the memory requirements but increase the number of key strokes. Therefore, it is not realistic for system design to achieve the best on all issues, such as three factors in this paper and unmentioned ones. What we should chase might be to make a balance for an acceptable compromise.

For heuristic evaluation results, each usability violation was categorized into 4 severity level according to its averaged rating score. They are catastrophic (rating > 3.5), major (2.5 <rating < 3.5), minor (1.5 < rating < 2.5), and cosmetic (rating < 1.5). Of 19 identified violations in total, there are 9 problems at the major level and 5 at the catastrophic level. These 14 problems consist of 4 Language ones, 3 Consistency violations, 2 Memory ones and each one in other five categories (Document, Error, Control, Flexibility and Minimalist), and 3 of 4 Language ones are usability catastrophes. All violations found in the first round of heuristic evaluation would be sequenced to steer enhancement of system usability.

To sum up, the task analysis and heuristic evaluation applied in this study can facilitate developers of volunteer medical incident reporting system at the initial stage of development cycle in fulfilling the users' needs and uncovering the flaws of usability concerns. Although it is not feasible to work out all the problems, these two steps will drive usability research into a system development cycle, especially for voluntary medical incident reporting system. As a result, usability problems could be iteratively identified and fixed, and users could be much easier and more satisfied of using voluntary medical incident reporting system over the time.

Future

The usability engineering is not a one-shot task but an iterative process with usability discovery and reinforcement. Furthermore, the development of a user-centered medical incident reporting system needs to establish a relation between different levels of users which is crucial to success of medical incident reporting applications. For instance, poorly unstructured incident datasets and lack system integration of the PSN have largely impeded system's usefulness. Much electronic medical

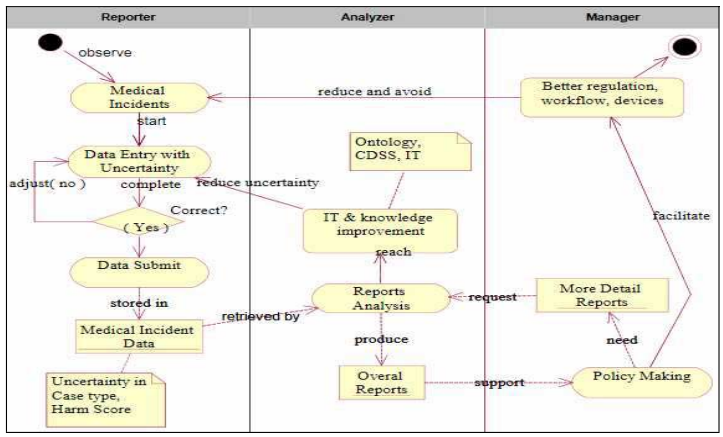

Figure 2-Iterative feedback cycle for voluntary medical incident repoting system

data have to be repeatedly entered into the PSN system and a big chunk of medical data in free text format shows inconsistency and impedes the application of data mining tools. Therefore, to advance our study we will emphasize collaborations between different systems and different types of users. The iterative development cycle shown in Figure 2 depicts collaborative feedback among three participating roles: reporters, analyzers and mangers. The reporters are in charge of data entry of observed medical incidents by reporting system. The quality of data stored in properly structured format is the key to validity of incident reports. The analysis reports will advance the applied technology and knowledge support for medical incident reporting for the purpose to diminish the uncertainty and other difficulties in reporting process. On the other hand, the analysis reports can be used to persuade managers of health unit to extend the usage of reporting system by administrative approaches, such as policy making. Ostensibly, the effective collaboration shown in Figure 2 could facilitate using and enhancement of voluntary medical incident reporting system. The more important is that the quality of care could be improved continuously with iterative enhancement of system performance and increasing use of reporting system.

Abstract

To meet the challenge of improving health care quality in urban, medically underserved areas of the US that have a predominance of chronic diseases such as diabetes, we have developed a new information system called CEDRIC for managing chronic diseases. CEDRIC was developed in collaboration with clinicians at an urban safety net clinic, using a community-participatory partnered research approach, with a view to addressing the particular needs of urban clinics with a high physician turnover and large uninsured/underinsured patient population. The pilot implementation focuses on diabetes management. In this paper, we describe the system's architecture and features.

Keywords:

Information systems, Chronic disease, Diabetes mellitus, Continuity of patient care, Disease management, Clinical decision support systems, Registries

Introduction

For every 1,000 patients who receive medical care in the US, it is estimated that only one patient receives this care at an academic medical center.[1] Informatics tools specifically designed to assist those clinicians who provide the bulk of patient care in non-academic medical settings could have a tremendous impact on improving healthcare quality. About 125 million people in the US suffer from at least one chronic disease.[2] In spite of this high prevalence, there is consensus that the quality of chronic care in most primary care settings is inadequate.[3] Factors contributing to this inadequacy include deficits in care coordination, lack of information and ongoing support for self-management, poor management of clinical information, and inadequate decision support mechanisms for providers of care.[4] These are further magnified in safety net clinics by high patient-to-physician ratios, limited access to care, lack of insurance, and under-insurance. Wagner's Chronic Care Model identifies clinical information systems as a key component in addressing chronic disease management.[4-6] In particular, clinical information systems that include registries are invaluable for collecting and managing data on chronic diseases, monitoring the health status of a clinical population, and assessing the effectiveness of a clinic's quality improvement efforts.[7] Although most studies of electronic disease registries have examined their use in managed care settings, at least one study has shown that it is feasible to develop electronic disease registries for use in safety net clinics that cater to uninsured and medically underserved patients.[8]

A recent first of its kind comprehensive survey of health information technology use among California community clinics suggests that while 96% of the clinics have implemented a diabetes registry, only 31% report that all providers use the registry.[9] Another study has shown that implementation of disease registries appears to be more successful in clinical settings that already have electronic health information systems versus clinical settings that utilize paper-based systems to record and track patient health information.[10]

Nine suggested features for electronic registries are: a) short training time and easily navigable screens, b) registry systems should be web-based, c) drop-down menus and logic checks, d) HIPAA compliance and adherence to internet security standards, e) support for multiple diseases/conditions, f) incorporation of clinical practice guidelines and reminders, g) support for creation of individual care plans and disease severity rankings, h) ability to print out summary data on care quality and patient outcomes, i) linked to *but not a substitute for* an electronic medical record.[7] An evaluation of three widely used registry systems: the Chronic Disease Management System (CDMS), the Patient Electronic Care System (PECS), and DocSite showed that none possessed all of the nine suggested features.[7] Other suggested features include real-time availability of data, the ability to search for and identify patients at risk for a given clinical condition, web-based links to diabetes guidelines (for diabetes registries), and the provision of feedback to providers to aid preventive and long-term patient care.[11]

Since a goal of some existing registry systems is to spur wide adoption in primary care clinics that may not have dedicated IT staff, they sometimes utilize file-based database management solutions geared for ease of use by lay-people (e.g., Microsoft Access). Unfortunately, these solutions may not offer robust patient data security or be scalable as a clinic's population grows. In addition, some of these registry systems make assumptions about the clinical setting, (for example, assump-

tions about how patients are assigned to primary care providers), that may not correspond with reality, resulting in a need for extensive customization in settings that may not have the requisite IT staff. Recognition of these issues and a desire to address them has led to a unique community-participatory partnered research collaboration between researchers at the Center for Biomedical Informatics at Charles Drew University (CDU) and clinicians at the Family Medicine Clinic of the Hubert H. Humphrey Comprehensive Health Center (HHHCHC). HHHCHC is a Los Angeles County Department of Health Services ambulatory care clinic that has approximately 13,000 annual patient visits and caters to a patient population that is 55% Latino and 37% African American, with 70% or more of the patient population lacking public or private insurance.

The Family Medicine Clinic at HHHCHC has attempted to utilize the Chronic Disease Electronic Management System (CDEMS) in the past for depression management. Recognition of the need for extensive customization of CDEMS was one of the factors that led to the current collaboration between CDU and HHHCHC. A goal of the CDU-HHHCHC collaboration is to develop a computerized system for managing chronic diseases in primary care settings that takes into account the socio-technical barriers to successful implementation and forges academic-community partnerships with community clinics that cater to medically underserved patients. The CDU Electronic Disease Registry to Improve Chronic Care (CEDRIC) is a chronic disease management system that has resulted from this effort.

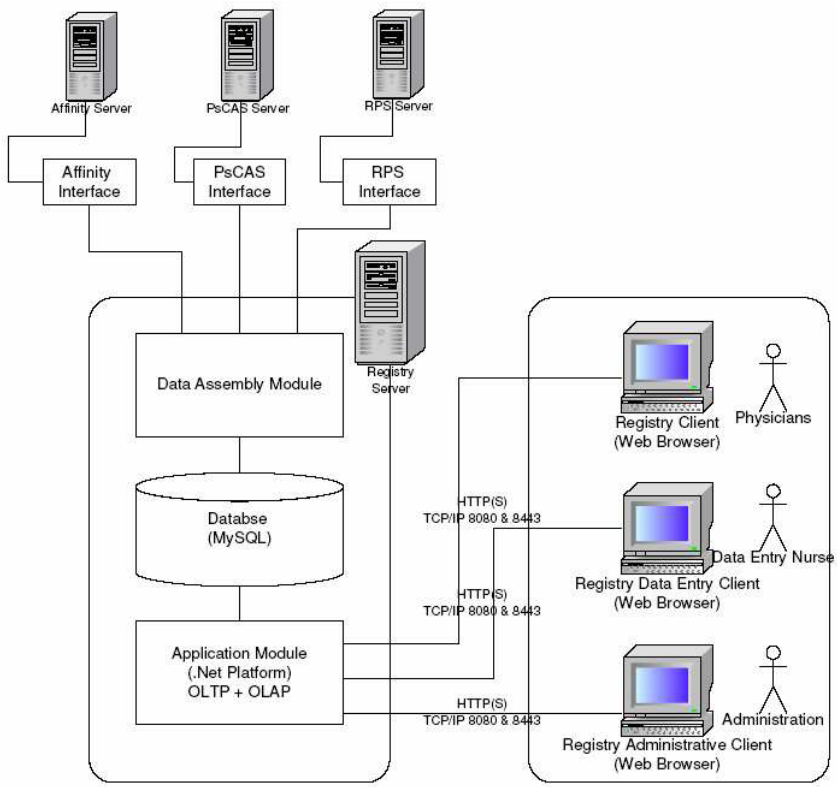

Figure 1- CEDRIC System Architecture

Materials and Methods

Through weekly meetings with clinicians at HHHCHC and researchers at CDU that have continued for over a year, key elements of a system for chronic disease management focused initially on diabetes were identified. Identified needs included: (1) robust system security, (2) access to data and system features based on a user's role as a physician, nurse or administrator, (3) system scalability and flexibility, (4) promotion of evidence-based medicine based on local and national clinical practice guidelines through the provision of automated system alerts and recommendations, (5) the ability to query and summarize pertinent information about an individual patient, (6) the provision of automated periodic reports for physicians, nurses and clinic administrators on patient lab results, care continuity, self-management, Hemoglobin A1c (HbA1c) levels, medications, and comorbid conditions, (7) a HbA1c monitoring service that enables interested clinicians to flag patients whose HbA1c levels they wish to monitor more closely, (8) the ability to track the homeless status of patients as this affects treatment options (the clinic refers homeless patients for social services prior to initiating treatment, since patients receiving insulin need access to refrigerators). While the clinic does not have a fully-integrated electronic medical record (EMR) system, it does have computerized patient scheduling, laboratory, medication, and referral systems. The need to interface with these existing systems was noted. The sociologist on the team, based on interviews with clinic providers and nursing staff, developed a workflow chart to outline the existing clinical flow of patients with diabetes in the family medicine clinic. This was done in order to understand how the CEDRIC system could be best implemented to fit into the existing clinical processes and workflow at the point of care since an understanding of workflow has been a feature of successful diabetes management systems.[12] Charting the workflow required a detailed understanding of the steps involved in a diabetic patient's visit to the clinic. We found that patient visits included the following four steps: 1) registration and financial screening at the general reception desk of the clinic, 2) initial assessment and review of vital signs by the vitalization nurse attendant, 3) visit with the clinician in the exam room, and 4) counseling and discharge by the post-visit nurse-counselor.

Results

CEDRIC has the capability to receive and process daily patient scheduling data and identify those patients with the chronic disease to be managed. The system is designed around a progress note that facilitates standardization of care for patients with particular chronic conditions. It is a database-backed web application utilizing the .Net framework, with C# and VB.Net as the programming languages and MySQL Server 5.0 as the database management system. MySQL was selected for its scalability, platform flexibility, security features, robust transactional support, data warehousing capabilities, and the fact that it is an open-source database management system. MySQL's storage-engine architecture allows the server to be configured for different applications - in our case, to support both the high-volume of transactional queries (OLTP) handled by CEDRIC via users' interactions with the progress note, and the high-speed analytical processing (OLAP) for patient care summaries/reports.

System Architecture:

CEDRIC system components include a registry server and several clients (see Figure 1). Within the server, a data assembly module is designed to collate electronic information from the clinic's health information (Affinity), referral (RPS), and medication (PsCAS) systems. It also checks for data inconsistencies and errors prior to data storage. CEDRIC's server utilizes MySQL for both transactional data processing and to support its data-warehousing environment for generating different clinical care reports. An application module that works in conjunction with a web server retrieves and processes data from the database, stores data to the database, constructs web pages containing requested information for presentation to the user, and implements logic for generating alerts and customized clinic-wide and clinician-specific core measure reports. These reports include patient summary reports, appointment reports for tracking care-continuity and on-demand registry queries. The CEDRIC system has three client categories; physician, nurse and administrator. The system display, including progress note, patient monitoring options, and care report options, is tailored to a user's login role. Users with two roles (e.g., physician and administrator) can interact with the system using either role. Figure 2 shows part of the progress note screen for a physician.

The alerts system is designed to automatically notify physicians when values corresponding to laboratory measurements are out of range, and when referrals and medication refills are overdue. The recommendation system for diabetes management is designed to deliver American Diabetes Association guideline recommendations as well as locally-tailored modifications to these guidelines on the appropriate course of action to be taken in response to alerts.

CEDRIC includes most of the suggested features outlined in the introduction. The feature not entirely implemented is linkage to an EMR system because HHHCHC does not currently have a fully-integrated EMR system. However, CEDRIC is designed to capture and utilize electronic data feeds from the different existing systems that handle patient scheduling, laboratory management, referrals, and medications. CEDRIC would be able to interface similarly with a full-fledged EMR system when the clinic chooses to adopt one.

Discussion

We have presented a summary of CEDRIC, a chronic disease management system developed through an academic center-community clinic partnership. The system implements most of the suggested features for an electronic disease registry as outlined in recent publications on the subject. A key aspect of system development was close collaboration between community clinicians and academic informaticians in identifying and addressing critical issues. We view this close collaboration as key in developing health information systems that are tailored to community health center needs, since many such centers do not employ informaticians, generally have small IT

budgets, and may not have in-house technical support to adapt existing generic IT systems to meet their unique needs. It is our view that information systems that meet the unique needs of community health clinics are more likely to be routinely used by clinicians in those settings. Support for management of chronic kidney disease, cardiovascular disease, HIV/AIDS and depression is planned.

Ongoing activities for CEDRIC include development of a data input module that supports both HL7 version 2.x and version 3.x messaging standards. The new module will accept several different data formats, including: i) HL7 v2.x compliant data, which mostly uses a textual, non-XML encoding syntax based on delimiters, and, ii) HL7 v3.x compliant data, which is based on a formal methodology (the HL7 Development Framework or HDF) and object oriented principles and is encoded using XML.

Future work will include a formal evaluation of the effect of system introduction and utilization on patient outcomes and the quality of care at the clinic. We also plan to make CEDRIC available for use to other safety net clinics.

Abstract

The diffusion of information technology (IT) in healthcare systems to support clinical processes makes the evaluation of physician and nurse post-adoption an important challenge for clinical information systems (CIS). This paper examines the relationships between the determinants of success of a CIS based on an expectation-confirmation paradigm in a cross-sectional survey performed at the Sherbrooke University Hospital (CHUS). 32.2% (161) of physicians and 27.1% (352) of nurses responded to the survey questionnaires. Results suggested that physician and nurse satisfaction is determined differently according to post-adoption expectations: compatibility, confirmation of expectations, usefulness, ease of use, and support. The best predictor of physician satisfaction was perceived usefulness (r=.25, p=.0003) whereas for nurses it was ease of use (r=.18, p=.0003). Confirmation of expectations was strongly associated with each post-adoption expectation and positions its importance in CIS design and redesign. This study draws attention to the differences between physician and nurse perceptions of information technology and emphasizes post-adoption evaluation to measure CIS success. Physicians and nurses post-adoption expectations were key factors to warn again potential discontinuance.

Keywords:

Clinical information system, Post-adoption behavior, Success dimension, Confirmation of expectation, Satisfaction

Introduction

Clinical Information Systems (CIS) have significant potential to improve clinical processes and patient satisfaction [1]. Analysis of the success factors is essential in assuring the initial success and survival of a system in clinical routines in order to achieve the health system objectives [2]. Many factors affect the CIS post-adoption process by health professionals; the understanding of a successful CIS implementation is critical to the improvement of health care services and future development of CIS. Furthermore, it is essential to integrate analysis of health professional expectations and satisfaction in post-adoption models, and to investigate the relationship between user characteristics, compatibility, perceived usefulness, ease of use, and user support. Several studies have shown the driving role of the compatibility [3], perceived usefulness and ease of use [4,5], and user support [2] in the evolution of the adoption process and IT diffusion in organizations. This integrative approach is supported by the combining of relevant constructs of these IS research models [4-6].

The CIS of the "Centre Hospitalier Universitaire de Sherbrooke" (CHUS) was developed relatively early, but has, from time to time, encountered resistance by professionals. The levels of use were very different from one unit to another, even though CIS aims to improve health care processes and the quality of health care systems at the CHUS. In this study, we attempt to integrate user characteristics, perceived ease of use, compatibility and support, into the expectation model in order to analyse the mechanisms through which physicians and nurses achieve their post-adoption decisions and satisfaction.

The choice of dimensions is aligned with managerial perspectives and, by their relevance and compatibility, with the action plans for the evolution of CIS at the CHUS. Each CIS success dimension was assessed in terms of the different viewpoints of physicians and nurses.

Materials and Methods

Clinical Information System and Setting

This study was conducted at CHUS, a 712-bed affiliate of the Faculty of Medicine, Sherbrooke University. The CHUS' healthcare organization is divided into 11 client programs. The electronic clinical information system (ARIANE) was installed in 1989 with a progressive implementation strategy. ARIANE is an integrated system, and supports the following clinical processes: (1) admissions, discharge and transfer (ADT), (2) electronic health records (EHR): laboratory, radiology and imaging, diagnostic test results, (3) partial computerized provider-order entry (CPOE) including laboratory and radiology tests, (4) clinical documentation (CD): patient demographic characteristics, (5) appointment and patient scheduling (APS). In clinical practice, physician notes, problem lists, medication lists, discharge summaries and nursing assessments are achieved on paper, as well as orders for medications. In general, the nurse's processes are less developed than physician's processes in the ARIANE

system. The clinician notes, medication orders and discharge summaries are digitized and made available through ARIANE. According to Jha *et al*, ARIANE is a system that evolves between "Basic EHR System without Clinician Notes" and "Basic EHR System with Clinician notes" [7].

Survey instrument

The survey was designed to measure user characteristics, CIS compatibility, CIS support, confirmation of expectations, perceived CIS usefulness, perceived CIS ease of use, and user satisfaction. A seven-point Likert-type (1=Strongly disagree, 2=Disagree, 3=Somewhat disagree, 4=Neither disagree nor agree, 5=Somewhat agree, 6=Agree, 7=Strongly agree) survey measured each dimension. All measurements were adapted from the previously validated instruments and modified based on the Clinical Information System. *User characteristics* asked users for personal information such as gender, age, whether working full or part-time, CIS training sessions and prior CIS experience. Items under *Compatibility* were adapted from Rogers and Moore [3,8,9]. *User Support* assessed the availability of CIS, help to access and understand CIS data, availability of assistance and training [2,9,10]. Items for measuring *Confirmation of Expectations* were adapted from Bhattacherjee and Van Der Meijden [2]. Four items were used to measure CIS expectations: compatibility, ease of use, usefulness and overall quality of the CIS [2,5]. *User Satisfaction* asked respondents to indicate their general satisfaction with the experience of using CIS, clinical information quality, reliability and user support quality. [2]. Scales for perceived CIS *Usefulness* and *Ease of Use* were adapted from previous studies on TAM [4,5,9].

Research model

According to the theoretical model used (Figure 1), the post-adoption user satisfaction is determined by the users' confirmation of expectations *(H3a)*, perceived usefulness *(H2a)* and ease of use *(H4a)*, compatibility *(H1a)*, support *(H5a)* and user characteristics *(H0)*. The perception of the usefulness is influenced by confirmation of expectations *(H3b)*, perceived ease of use *(H4b)*, compatibility *(H1b)* and support *(H5b)*. The confirmation of expectations *(H3c)*, compatibility *(H1c)* and support *(H5c)* directly influences perceived ease of use. In this model, the degree to which health professional expectations are confirmed is affected by both compatibility *(H3d)* and user support *(H3e)*.

Administration procedure

A cross-sectional field survey was conducted at the CHUS. We selected the CHUS to perform this study because its organization is positioned in the Post-Adoption phase for the last 5 years. The study targeted physicians and nurses working part-time or full-time at the CHUS, and used one component of CIS to support a clinical process. The survey questionnaires were anonymous and sent out to all program clients, between December 2007 and January 2008. Participants systematically received bi-monthly response reminders. In all, 1800 survey questionnaires were sent to physicians (500) and nurses (1300). 32.2% (161) of physicians and 27.1% (352) of nurses responded.

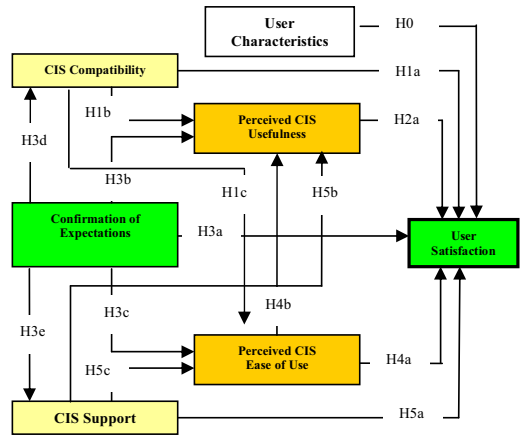

Figure 1- Theoretical Model

Data analysis methods

In the pre-test phase, the questionnaire was administered to a small target group (4 physicians, 8 nurses), in order to verify clarity of the questions. The reliability and validity of the items measuring the various elements was evaluated using Cronbach's alpha [11]. As shown in Table 1, the values were either close to or above 0.70. These results were acceptable [12]. For each dimension, we computed an aggregated variable and presented descriptive statistics, with mean and standard deviation. The mean deviation for physicians and nurses were compared by F tests. To address our research hypothesis, we performed separate multivariate regression analysis, as recommended by *Gefen* when the sample size is too small to use advanced statistical approaches such as structural equation modeling [13]. Analyses were performed using the statistical packages Statview® and Stata®.

Table 1-Validity of the instrument (Cronbach's Alpha)

Dimensions *(Items Number)*	**Physicians** (n=161)	**Nurses** (n=352)	**Total** (n=513)
Compatibility *(3)*	0.80	0.78	0.92
Confirmation of expectations *(4)*	0.96	0.93	0.95
User support *(4)*	0.80	0.78	0.74
Perceived CIS ease of use *(4)*	0.94	0.93	0.93
Perceived CIS usefulness *(4)*	0.94	0.89	0.91
User satisfaction *(4)*	0.82	0.79	0.80

Results

Users' characteristics

The sample consisted of 118 physicians, 43 residents, 324 nurses and 28 auxiliary nurses (table 2). Only 25.0% ($p<.0001$) of the respondents were male, working full time 74.5% ($p<.0001$) and having received prior CIS training 80.9%. The respondents averaged 40.1±11.4 ($p<.0001$) years of age and seniority at work at the CHUS of 14.1±10.5 years ($p<.0001$). The perception of CIS experience differed between physicians and nurses ($p=.0138$).

Compatibility

The items concerning CIS compatibility received very good scores (4.59±1.38) without any difference between health professionals (Table 2).

Table 2- Factors describing the compatibility dimension - Means (SD)

Using CIS is compatible with or (fits into)…	**Physicians** (n=161)	**Nurses** (n=352)	**Total** (n=513)
All aspects of my work	4.76(1.58)	4.66(1.45)	4.69(1.50)
My Work habits	4.55(1.56)	4.62(1.45)	4.60(1.49)
Organization of my work	4.39(1.60)	4.53 1.41)	4.49(1.47)
CIS Compatibility§	**4.57(1.51)**	**4.60(1.32)**	**4.59(1.38)**

§= Aggregated variable; Scale: 1=Strongly disagree to 7=Strongly agree

Confirmation of expectations

The post-adoption expectations such as compatibility (4.38±1.30) and perceived usefulness (4.64±1.27) did not differ, while perceived ease of use (4.60±1.21, p=.0085), quality of the CIS (4.54±1.27, p=.0199) and aggregated variable (4.54±1.18, p=.0230) scored higher on the scale for nurses (Table 3).

Table 3- Factors describing the expectations dimension - Means (SD)

The CIS…..was better than what I expected	**Physicians** (n=161)	**Nurses** (n=352)	**Total** (n=513)

*§= Aggregated variable; * p<.05; Scale: 1=Strongly disagree to 7=Strongly agree*

User support

CIS support (4.44±1.07, p=.0002) was relatively low according to the CHUS IT objectives (Table 4). However, physician perception in appreciation of availability of assistance (p=.0028) and training (p<.0001) ranked higher than nurses.

Table 4- Factors describing the user support dimension - Means (SD)

	Physicians (n=161)	**Nurses** (n=352)	**Total** (n=513)
CIS availability when I need it	4.38(1.38)	4.41(1.41)	4.40(1.40)

CIS Support§*	**4.66(1.03)**	**4.34(1.07)**	**4.44(1.07)**

*§= Aggregated variable; * p<.05; Scale: 1=Strongly disagree to 7=Strongly agree*

Perceived CIS ease of use

The aggregated variable physician (5.17±1.24) perceived CIS ease of use seemed slightly higher than that of the nurses (5.09±1.18). Overall, the items of this dimension were relatively high and not significantly different among health professionals (Table 5).

Table 5- Factors describing the ease of use dimension - Means (SD)

	Physicians (n=161)	**Nurses** (n=352)	**Total** (n=513)
Simplicity	5.19(1.30)	5.23(1.18)	5.22(1.22)
Comfortable	5.19(1.30)	5.10(1.26)	5.13(1.27)

CIS Usefulness§	**4.79(1.57)**	**4.59(1.20)**	**4.65(1.33)**

§= Aggregated variable; Scale: 1=Strongly disagree to 7=Strongly agree

User satisfaction

Physicians (4.79±1.28) were more satisfied with the quality of support than nurses (4.36±1.30, p=.0006). Overall, all professionals at the CHUS were satisfied with their CIS experience (4.76±1.04). For the other parameters, such as quality and reliability, both groups ranked similar (Table 7).

Table 7- Factors describing CIS user satisfaction dimension - Means (SD)

I am satisfied with…..	**Physicians** (n=161)	**Nurses** (n=352)	**Total** (n=513)

User satisfaction§	**4.83(1.13)**	**4.72(1.00)**	**4.76(1.04)**

*§= Aggregated variable; * p<.05; Scale: 1=Strongly disagree to 7=Strongly agree*

Model testing results

The regression results shown in Table 8 corresponded to the

model shown in Figure 2, based on the whole group of users (n=513). The model explained 68%, 53% and 59% of the variance of satisfaction for physicians, nurses and the whole group, respectively.

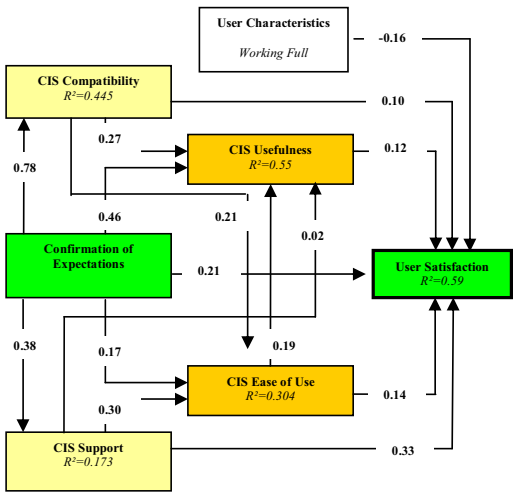

Figure 2- Model Testing Results (Total n=513)

The perceived usefulness (r=.25, p=.0003) was associated with physician satisfaction while perceived ease of use (r=.18, p=.0003) and compatibility (r=.10, p=.009) influenced nurses satisfaction. User support and confirmation of expectation were strongly correlated with physicians' and nurses' satisfaction. Compatibility, confirmation of expectation and ease of use were significant determinants of perceived usefulness. The explained percentage of variance was relatively high (≥48%). Compatibility (r=.21, p<.0001), confirmation of expectations (r=.17, p<.0001) and support (r=.30, p<.0001) explained 30.4 percent of the variance of perceived ease of use. Confirmation of expectations explained 63 percent of the variance in CIS compatibility for physicians. Furthermore, confirmation of expectations was most strongly correlated with CIS support for nurses.

Discussion

This study examined relationships between post-adoption expectations and satisfaction based on a model of confirmation of expectations. Results suggested that the confirmation of expectations was a relevant determinant of perceived usefulness, ease of use, compatibility and user support and the explained variances were relatively acceptable. The best predictor of a physician's satisfaction was perceived usefulness whereas for nurses it was perceived ease of use. Paré *et al* showed that clinician satisfaction was correlated with confirmation of expectations regarding the impacts of a PACS and perceived usefulness [14]. Thus, physicians are satisfied when the CIS provides desirable utility to their practice, and nurses when the CIS is easy to use in the nursing processes [15]. In a previous study we found that perceived CIS usefulness, perceived CIS quality and service quality had a significant effect on physician and nurse satisfaction [10]. Lee *et al*. reported that physician satisfaction was associated with ease of use, frequency of use, response times, and user characteristics [16]. Results also demonstrated

CIS= Clinical Information System; NS p>0.05 §= Aggregated variable; H=Hypothesis

the importance of perceived ease of use in mediating the relationship of user support, compatibility and confirmation of expectations on satisfaction. For the nurse group, perceived ease of use had positive effects on perceived usefulness, according with TAM in pre-adoption [4]. As shown by Chismar *et al*, this relationship had no significant effect among the physicians, especially in post-adoption [15,17]. These findings showed that physicians and nurses at the CHUS are not experiencing the same dependence on CIS in their daily tasks. Currently, the description of the nursing processes was not electronically documented in the CIS [18]. CPOE functions are available for the laboratory and radiology orders; medication orders are input by pharmacy staff but are not yet introduced into the clinical processes. The implementation of clinician notes and medication orders associated with clinical decisions supporting (CDS) faced significant challenges for the IT practices at the CHUS in particular as well as the province of Québec as a whole. Another plausible explanation might be that nurses were considering CIS to be easy to use in their clinical processes and that they depended more on user support than physicians [10]. The compatibility influenced user satisfaction toward perceived ease of use. Chau *et al* found that compatibility was a significant determinant of perceived usefulness but not of perceived ease of use [15]. Several limitations of our study have to be emphasized. The response rate was low by physicians (<15%) and nurses (<24%). The relatively low R^2 values of CIS support and perceived ease of use compared with prior studies suggested the potential limitations and possible omission of factors important to the healthcare post-adoption context.

Future perspectives of this work could be the consolidation of the CIS post-adoption model and then evaluating its applicability in other academic hospital contexts using structural equation modelling to test and analyse post-adoption network causalities.

Conclusion

The findings of the study provide insights and implications relevant to CIS post-adoption research, communication and articulation of salient post-adoption expectations and health IT management.

Acknowledgments

I wish to express my gratitude to the personnel of CHUS, in particular M. Pierre Tétreault for the data collection, and especially to the health executive in each unit.

Abstract

We propose an innovative approach for measuring real-time operational load within emergency departments. Medical informatics, operations researchers, and other decision makers in the health care field have yet to come to an agreement regarding standardized matrices for measuring operational load within emergency departments. As a result, it is difficult to develop methods and approaches for reducing operational load. We propose a flexible framework based on neural networks. These networks can calculate user-tuned load value, based on a set of well-defined operational and clinical indicators. The operational load value is calculated by learning the weights of the raw operational indicators within a particular emergency department.

Introduction

The rising cost of healthcare services has been a subject of mounting importance and much discussion worldwide. Ample explanations have been proposed, yet regardless of their cause, rising costs impose pressures on healthcare providers to improve the management of quality, efficiency, and economics for their organizations. Significant attention has been given to the question of how to reduce this cost in the healthcare domain Hospitals are one of the major players in the provisioning of health services and within hospitals, emergency department (ED) overcrowding has been perhaps the most urgent operational problem [1, 2, 3]. Overcrowding in hospital EDs leads to excessive waiting times and repellent environments, which in turn cause: (1) poor service quality (clinical, operational); (2) unnecessary pain and anxiety for patients; (3) negative emotions (in patients and escorts) that sometimes lead to violence against staff; (4) increased risk of clinical deterioration; (5) ambulance diversion; (6) patients leaving without being seen (LWBS); (7) inflated staff workload; and more [4].

In order to reduce the occurrence of overcrowding in hospital EDs and optimize ED operations, we need to understand what the current crowding load level is. This means that it is necessary to decide how load on various resources should be defined, to whom it should be presented, and how it should be demonstrated. This task is difficult for several reasons. First, establishing which parameters contribute to the load is complex and subjective. Second, even once the parameters are established, assigning a level of contribution to each one is difficult, due to the varying conditions in each hospital, and to the perceptions of different management teams. Third, the ED is a complex environment that involves various types of entities (e.g., physicians, nurses, patients, executives); each of whom may define the load function differently. Clearly, load has to be a usage-dependent function. Fourth, the definition of load changes from time to time and needs to be updated periodically. Fifth, due to the large number of quickly-changing events and factors that are critical to saving lives, displaying a real-time snapshot of the load in the system is critical. This snapshot must be displayed in such a way that decisions based on current load can be made quickly and easily.

Our Contribution

In this paper, we present Measuring the Emergency Department Adaptive Load (MEDAL), a flexible and adaptive system that enables the calculation of user-tuned load in emergency departments, using various types of inputs and defined load functions. Tuning for the needs of the user makes the system user-specific, resulting in a load score that directly reflects the high level of input. The system is based on artificial neural networks [5] and enables the following: (1) a static mechanism for an explicit definition of load functions; and (2) a dynamic learning mechanism that enables the system to adapt to the perceptions of users with no explicit load function definition.

The dynamic learning mechanism allows the system to present different load values for the same objective situation. This is particularly useful for understanding the difference in operational load perception by physicians, nurses, patients, and the ED management.

MEDAL is a highly adaptable load measurement tool that, by scarifying rigid definition for high flexibility, allows users to analytically compare various situations, and to reach informed decisions regarding the appropriate steps to take in order to reduce the ED load.

The paper is organized as follows: the Methods section describes the main idea of our proposed solution, along with the technical details on how the system was built. In the Results

section, we describe our main results achieved from implementing load profiles. The Discussion section deals with the benefits of using our system in diverse and dynamic environments for process optimization and planning. We then conclude with a summary of the approach, the benefits of system use, and directions for future research and development.

Methods

The calculation of operational load in emergency departments and its presentation are highly important, yet difficult tasks, for improving efficiency. To that end, we developed MEDAL, a flexible framework for measuring subjective load, using iterative user feedback. MEDAL can be adapted for any user preference and view of the load in specific environments. We describe the main idea on which the design of the system was based and developed, and then elaborate on the technical implementation details.

Main Idea

MEDAL is a flexible and configurable framework for measuring ED load. By default, our framework receives an extensive set of raw indicators as input. These indicators were reported in the literature [6] as a consensus for the set of measures that are important for the calculation of ED load. Moreover, this set of indicators can easily be modified according to user needs. Also, our framework receives operational events from the existing ED infrastructure, processes them, and calculates the time-specific input indicator values. The core of our framework is a learning neural network mechanism that enables the following main features: (1) Users can modify the set of basic indicators collected from the ED infrastructure. (2) Users can configure the system with any kind of load function. (3) In cases where the load function cannot be defined explicitly, our framework provides an adaptive mechanism that learns the desired load function autonomously. This is done by learning from the user feedback on the calculated load, while viewing snapshots of ED states and the corresponding calculated load. (4) The system also offers advanced capabilities for tracking the origin of the load status and for understanding its cause at different levels of granularity. Moreover, the system can provide specific alerts regarding the high load values at various predefined internal points, even if the total load in the system is low. (5) The system enables comparison among various calculations of load, according to the perception of different roles in the ED. We further demonstrate and discuss these features in the Results section.

We now elaborate on the technical details that served as a basis for the development of the proposed system.

Implementation Details

Load Function Definition

Our framework provides a simple way to define any explicit load function, based on canonical indicators and the display of that function's behavior during different time frames. This process is described below and shown in Figure 2.

Learning Unknown Load Functions with Neural Networks

Due to the complexity of the ED environment, explicitly defining the load function is often not useful. Therefore, machine learning techniques should be harnessed to solve these issues. We chose to use the artificial neural networks [5] as our basic mechanism. These systems are flexible for composition, adaptive over time, meaningful for the user, and enable the definition of complex relationships (e.g., nonlinear) between inputs and outputs.

We first provide a theoretical background on neural networks and then explain how these were harnessed to solve the problem raised in this paper.

Neural Networks – Theoretical Background

Artificial neural networks [5] are mathematical representations of complex mathematical functions. They are composed of units named perceptrons (Figure 1a), and arranged as a multi-layered feed-forward network (Figure 1b), in which the outputs of one layer are the inputs of the next layer. This type of learning machine was inspired by the brain structure. These machines are successfully used in many applications, such as pattern classification, dimensionality reduction, and function approximation [7, 8, 9]. Because of the origins of the machines' design, the nodes in such networks are often called *neurons.* The machines' greatest advantage is their simplicity (in both representation and learning). In addition, the number of required training examples (that is relative to the network structure) is not high compared to other machine learning solutions.

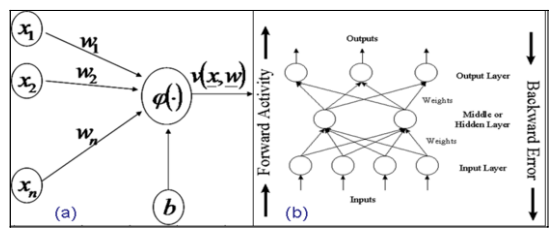

Figure 1- (a) single perceptron; (b) Multi-layer network

Each perceptron is composed of n inputs, $x_1, x_2, ..., x_n$, n weights $w_1, w_2, ..., w_n$ and an activation function $\varphi(\cdot)$. The output of the unit is $v(\underline{x}, \underline{w}) = \varphi(\underline{x}^T \underline{w})$, where $\underline{x} = (1, x_1, ..., x_n)$, $\underline{w} = (b, w_1, ..., w_n)$. Examples of activation functions are sign ($\varphi(u) = sign(u)$), linear function ($\varphi(u) = u$), and logistic function ($\varphi(u) = 1/(1 + e^{-u})$). The type of activation function affects the ability of the network to learn and is application-dependent. The units in different layers are connected in a feed-forward style to determine the network structure (see Figure 1b). The exact structure is also application-dependent, and in many cases, domain knowledge can help to determine this structure.

Given a training set of the form $(\underline{X}_i, y_i)_{i=1}^{M}$ in which $\underline{X}_i \in \Re^n$ is the input to the network and $y_i \in \Re$ is the expected output (or target function) of the network, the back propagation algorithm [5] can be used to find a set of weights that minimizes the mean square error (MSE) between the expected output and the current calculated output. There are two types of learning—offline (or batch) learning, and online learning. In offline learning, the entire training set is given in advance. In each iteration of the back propagation algorithm, all of the examples are taken into account when updating the weights. In online learning, the examples are given one after the other, and each learning iteration depends on the current example only. Online learning is typically used when the environment changes over time, and when the network is trained to fit those changes.

Harnessing Neural Networks to Calculate Load in the ED

To demonstrate the advantages of our methodology, we built a neural network that represents the collective knowledge presented in the exhaustive indicators review paper [6]. We used it as our basic network for the load calculation (see Figure 2).

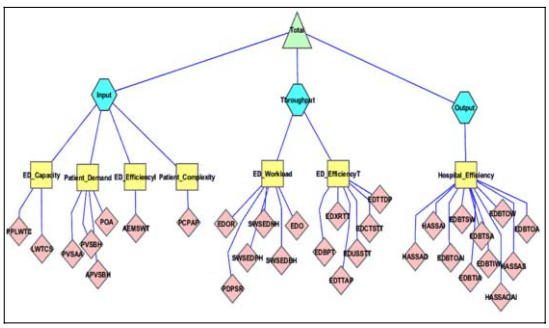

Figure 2- ED Neural Network View: The triangle is a total neuron, hexagons are the stage neurons, rectangles are the concept neurons, and diamonds are input indicator neurons

For the set of inputs, we took the set of indicators that were defined in the review paper and combined and ranked them in a hierarchical manner. The hierarchy in the network consists of four main layers: 1) ***Indicators Layer:*** This layer is the set of inputs, and consists of 31 nodes corresponding to 20 indicators that appeared in the review paper [6]. Several indicators were spliced to match their definitions. For example, indicator "*ED Throughput time*" was spliced into two nodes: one for admitted patients and one for discharged patients. Others were omitted due to the lack of appropriate input simulation data. We made minor modifications to the network, as suggested in the paper, based on additional data we could collect by using a simulator presented by Sinreich and Marmor [1]. This simulator, also used by Wasserkrug et al [10], is based on a canonical ED model, which was generated based on real-life observations within numerous hospitals. 2) ***Concepts Layer:*** The 31 indicators in the indicators layer are connected (each indicator to a single concept) to the following six concepts: patient demand, patient complexity, ED capacity, ED efficiency, ED workload, and hospital efficiency. The hospital capacity concept was omitted due to the lack of appropriate data. The *ED efficiency* concept was divided into two sub-concepts to serve the input and the throughput separately. This modification was made to keep the tree-like structure of the network. We will explain the importance of that structure later in this paper. 3) ***Operational Stages Layer:*** The seven concepts are connected (one concept to each operational stage) to the following three operational stages: input, throughput, and output. 4) ***Load Score Layer:*** This layer is the output layer and consists of a single node representing the total load function score.

As described above, we can learn the target function using either the offline or online method. Both approaches require knowledge of the true target function values on some set of input vectors. This means that we have to present each such vector to the expert user and receive the desired function value in return. However, this flow cannot be used for two main reasons. First, input vectors are often too long for human perception and embedding. Second, The desired value of the target function cannot be explicitly calculated. In the following paragraph we describe how we handle both of these challenges.

Instead of presenting the input vector itself, we present current ED status using a patient-centric dashboard (Figure 3). The patient-centric dashboard provides ED staff with information about the status of each patient in the ED. Patient status is usually presented as a row within a table-like view. This approach is commonly used in EDs around the world. By working with the patient-centric dashboard, the ED staff gains total insight regarding the operational ED load. We use this insight to enter feedback into the network, thus enabling it to learn the required load function. The user provides feedback by using the dedicated feedback buttons. For example, if the user *feels* that the represented load is far below the desired value, he pushes the larger "+" button, increasing the current load by 10% increments. A similar update process (+1%, -1%, -10%) works for other feedback buttons. Clearly, such a feedback system can be easily implemented in any existing dashboard without significant changes.

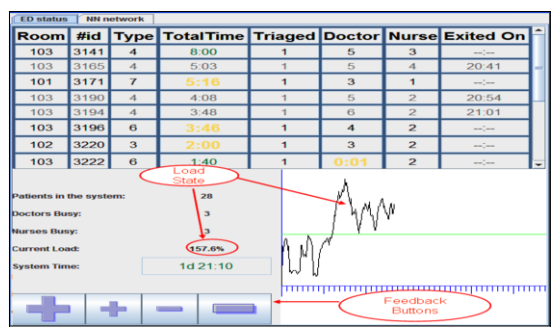

Figure 3- Dashboard snapshot. Load value (black line) is calculated as the percent of the average (green line)

Tracking Load and Bottlenecks

In our system, every neuron has an explicit operational meaning. Our neuron network design keeps the tree-like neuron hierarchy instead of the usual all-to-all connections. This allows each neuron to preserve its operational meaning during the learning process. Conserving the tree-like structure allows the user to track the current load back into the network and to gain a deeper understanding of the current load status (Figure 4). Moreover, we can get an alert from any hierarchy level in the system if a certain neuron becomes overloaded. For example, if the current system load is only 40% of the average but the CT room is overcrowded due to lack of personnel, the appropriate neuron's status will reach the high mark, and can alert the user, provided the neuron was preconfigured accordingly. As a result, the ED manager may react by temporarily adding to the CT room staff.

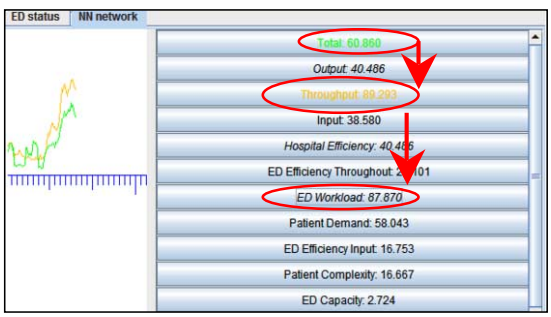

Figure 4- Tracing load: Green line indicates total load, orange line indicates throughput; the rise in the total load was clearly caused by increasing the throughput input neuron. We can trace it further and deduce that the peak in throughput was caused by elevation of the ED workload concept neuron

Comparing Different Views on ED Load

Our framework allows dynamic learning based on feedback from different user groups. We can calculate and present several different load views for the same objective situation. For example, measuring the current ED load as perceived by doctors, nurses, and patients, or even by a single individual such as the ED manager, could have interesting applications. Having an option for defining a subjective load function that best reflects the actual load experienced by a given user group could be very useful, as well. In the next section, we investigate and demonstrate the differences in load perception for three user groups: ED Doctor, ED Nurse, and ED Patient, as an example of this application.

Results

To demonstrate the system's ability to reflect subjective load, we identified three possible group types: nurse, doctor, and patient. The user profile reflects operational load as it is being experienced by a given group, or even by a specific individual within the ED. User profiles can be statically defined by fixing weights on relevant neurons, or preferably, by dynamically learning the user profile. Dynamic learning involves capturing user feedback from a specific user or user group associated with a relevant profile. To achieve this, we generated operational data using a simulator tool [1] and defined subjective target load functions for three group types. Nurse and doctor target load functions were defined as the average occupation ratio during a time period. Patient target load function was defined as the ratio of a patient's waiting time to the patient's total staying time in the ED (Figure 5).

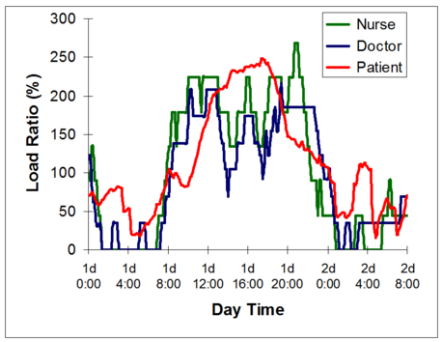

Figure 5- Simulated nurse, doctor, and patient profile behavior, where 100% is the average daily load

Figure 6 presents results from running the system multiple times and dynamically learning the three groups' profiles. Each profile is comprised of the weights of major neurons learned by the system.

Raw Indicator \ Profile	Nurse	Doctor	Patient
Patient Volume standardized for Bed Hours	42%		76%
Summary Workload standardized for ED Bed Hours	18%	45%	
ED Bed Placement Time	12%	30%	8%
ED CT service Turnaround Time	28%	25%	16%

Figure 6- User profile comprised of major raw indicator weights learned by the system

We can see that all three profiles show reasonable behavior when comparing time of day and when comparing the profiles to one another. When the system is overloaded, all users feel it. However, the load experience is different for each group. For example, doctors need to stay later than nurses at the end of the day and to close all open cases. Thus, the load on them decreases later than it does for nurses. On the other hand, triage, served by nurses, is the first station in the patient flow. Hence, the nurses' operational load starts earlier. These examples demonstrate that there are indeed different weights on the neurons, emphasizing the need for subjective load scores for the same objective ED state.

Discussion

In this paper, we introduce MEDAL, a flexible system for the estimation and measurement of load in hospital emergency departments. The development of MEDAL stemmed from the understanding that ED load is influenced by a large number of factors that are difficult for both humans and machines to consider together. Solberg et al., [6] gathered 74 experts to collect a set of 113 measures affecting the load in EDs, of which 38 were selected through a discussion and rating process. This set of measures was divided into three categories (input, throughput, and output) and seven concepts (patient demand, ED capacity, patient complexity, ED efficiency, ED workload, hospital efficiency, and hospital capacity). While Solberg provides a comprehensive set of load measures and concept categories, he does not suggest a straightforward way to use these measurements in real-life scenarios. Our experience shows that establishing a standard operational load model that fits all EDs is not practical, due to the inherent differences among them.

MEDAL is a flexible and adaptive framework for load calculation that comes with a set of initial measures (the measures that appear in the abovementioned paper) and a set of load functions. The framework can be easily enhanced with additional measures and load functions. Moreover, the system includes a mechanism to learn the load function from the user, in cases where this could not be explicitly defined. This learning mechanism is used to define user profiles, each with its own view and requirements, from the calculation of load in the ED environment. Figure 5 shows the load calculated for three possible profiles. It shows that all measures estimate the load quite similarly, meaning that when there is a burden on the hospital, all relevant entities (e.g., staff members, patients) are affected. However, this system allows users to distinguish between the load pressures felt by these entities. Measuring load is a crucial step for optimizing ED operation. This measure of load can be used in various ways. First, it can be used to optimize the staff routing inside the ED at times of high load levels. This could of course reduce the burden on hospital departments. Using the offline method, load calculation can be used to provide detailed planning for different staff members in the ED (e.g., nurses, physicians). The MEDAL approach may also be applicable to other hospital wards and even to other industries. Providing a highly adaptable measuring tool, may prove useful in many situations in which global agreement about measured indicators is out of reach. Our work on this issue is beyond the scope of the current paper.

Conclusion

In this paper, we presented MEDAL, a novel, flexible, adaptive framework for user-specific load definition and calculation. The major advantages of the presented system are its flexibility to fit specific user needs, and its ability to handle and learn from highly undefined data that represents subconscious user perceptions**.** The implementation of the method is straightforward and can be easily integrated in any current ED dashboard system. The received user-specific load score can also be used for operation optimization and for providing advice to ED personnel. Moreover, measuring operational load, while taking into account user-specificity, is an interesting research direction in and of itself.

What effect does electronic ordering have on the organisational dynamics of a hospital pathology service?

Andrew Georgiou[a], Johanna I. Westbrook[a], Jeffrey Braithwaite[b]

[a] *Health Informatics Research & Evaluation Unit, Faculty of Health Sciences, The University of Sydney, 1825, Australia*
[b.] *Centre for Clinical Governance Research, Australian Institute of Health Innovation, Faculty of Medicine University of New South Wales 2031, Australia*

Abstract

The aim of this triangulated (multi-method, multi-setting, multi-staged) study was to identify the consequences of an electronic ordering system on the functioning and organisational dynamics of a hospital pathology service. The study was carried out in five pathology departments during the period August 2005 to April 2006. It included five focus groups involving 21 participants and 67 interviews with 38 participants, along with a total of 21 hours of observation. The findings revealed three key themes with implications for the functioning and organisational dynamics of the pathology service. These included: a) work process changes that affect the output of the pathology laboratories; b) temporal considerations, particularly as they related to efficiency of laboratory processes; and c) communication channels and the resulting changes in the mode of information exchange and communication. These themes emerged from a close analysis of the contextual setting of each department. Successful CPOE implementation should be premised on a solid understanding of the organisational, communication, information and temporal circumstances in which the system will operate.

Introduction

Pathology services are made up of a complex array of organisational structures and laboratories, each with idiosyncratic work practices and specialised test procedures contributing to the prevention, detection and management of disease [1, 2]. Historically, pathology has been at the forefront of health information and communication technologies (ICT) innovation [3, 4]. This is because of the significant contribution that ICT makes to the management of the service's information-intensive work processes.

In the past, the impact of new pathology systems (eg, the introduction of a new laboratory information system) has generally been confined within the boundaries of the department, helping it to improve efficiency and effectiveness. The difference with Computerised Provider Order Entry (CPOE) is that it is not laboratory centric, but incorporates a wide spectrum of systems including imaging, clinical procedures, consultations and medications along with clinical documentation systems, which by definition increases interaction and integration across hospital departments by facilitating greater access to shared information and expanded communication channels [5]. New ICT systems such as CPOE have the potential to act as catalysts for changing interactions within the hospital, affecting the nature and definition of jobs and work processes [6]. To date these areas of impact have received limited research attention [7]. The aim of this qualitative study was to identify the key consequences of CPOE on the functioning and organisational dynamics of different departments of the pathology service through a comparison of work processes before and after implementation of the system.

Material and Methods

Research setting

This research was carried out in a pathology service employing over 300 staff located at a major metropolitan tertiary referral hospital in Sydney, Australia. The service covers a broad suburban network comprising seven major hospitals. In November 2005 the pathology service's laboratory information system was replaced by the Cerner Corporation's (Kansas City, USA) Pathnet system which automates clinical and managerial pathology data processes. This was integrated into a hospital-wide PowerChart (version 2004.01) in January 2006. Ethics approval for the study was provided by the relevant Area Health Service ethics committee.

Research design

The study was carried out across five pathology departments (Clinical Chemistry, Haematology, Central Specimen Reception, Microbiology and the Blood Bank) during the period August 2005 to April 2006. It included five focus groups involving 21 participants and 67 interviews with 38 participants. Four focus groups and 10 interview sessions were transcribed resulting in 232 A4 pages (94,198 words). All initial focus group and interview sessions were semi-structured and used a set of questions which explored participants' understanding and expectations of the new system, along with the impact they expected the system to have on their work and

relationships with professionals across the hospital. These initial expectations were then followed up as a means of exploring what happened, how it happened and why it happened following system implementation. The interviews and focus group discussions were supplemented by 22 observation sessions amounting to 21 hours.

Participants in the study were chosen on the basis of their experience and knowledge of the topic under investigation and their potential to help in the testing and scrutiny of emerging hypotheses [8]. This included 24 laboratory scientists, 18 technicians and 11 other pathology and management staff.

Analysis

Data collection and analysis were carried out concurrently and used NVivo 2.0 software to initially code transcriptions and then refine them into analytical levels related to the research aim. All quotes presented in this paper are provided verbatim as a means of conveying the contextual richness of the findings. A research log containing observation and interview recordings along with reflections on the investigation process was maintained throughout the course of the study. Closure was achieved when it became clear that sufficient data had been gathered to render the study phenomenon coherent and explicable [9]. Further data collection would have realised redundancy.

Results

Contextual make up of pathology settings

The Central Specimen Reception (CSR) can be described as the receiving dock for pathology laboratory specimens. It is also responsible for organising the collection of specimens from patients across the hospital by a team of blood collectors. Specimens are passed on to departments such as Clinical Chemistry and Haematology. Clinical Chemistry undertakes the analysis of blood and other body fluids from chemical components, while Haematology is the study of blood and its cellular elements. Both departments deal with a large proportion of urgent and life threatening tests, the bulk of which emanate from critical care units and the Emergency Department where patient treatment is often reliant on laboratory results. This means that issues like turnaround time (the time taken for a request to be processed and a result issued) are an organisational priority.

In contrast the Microbiology department deals predominantly with diseases caused by infectious agents (eg, bacteria, viruses, fungi and parasites). These agents require time to grow before an appropriate test result is available. Consequently, for Microbiology the concept of timeliness has a different contextual meaning from that of the Clinical Chemistry or Haematology department. The role of the Blood Bank is to provide compatible blood components for patients. This involves blood grouping, antibody screening and identification and pre-transfusion testing. For both departments the existence of robust communication channels with clinicians is an important aspect of their work. In the Blood Bank this meant a high reliance on the telephone and fax machine to order, confirm and send blood products. For Microbiology, their communication channels include the provision of reliable patient-centred information which can make a vital contribution to the department's test analysis, interpretation and reporting.

Changes in work practices

For CSR, the new system had minimised their previously cumbersome data entry tasks and enhanced the efficiency of work processes leading to improved levels of data accuracy and fewer incidents of test request duplication. These work process improvements were particularly evident in the changes that occurred in the department's blood collection procedures (see Table 1). In the past the collectors headed straight off to the wards where they were required to sort and verify the handwritten requests, identify any duplicates and then take blood specimens from patients which entailed a number of handwritten tasks. The new system provided a printout to the laboratory eliminating the need to sort out any duplicates. While this new procedure slightly increased the amount of time collectors spent in the laboratory to identify and organise their print outs, it resulted in the removal of a number of handwritten procedures leading to a significant decrease in the time spent on the wards. Blood collectors also reported that the new system eliminated the need to handwrite patient information and identification details through the provision of printed labels which they felt significantly reduced the possibility of making a mistake.

Table 1- Representative selection of verbatim quotes from participants

Work practices	"So even though it seems more time consuming, when they get to the ward it's a quicker process." (CSR participant)
Temporal considerations	"A lot of our work is STAT [urgent and life threatening] work, so the turnaround time is expected to be within the hour for the majority of the work. Biochemistry [Clinical Chemistry] have that issue as well". (Haematology participant) "We did try to flowchart all the processes in the lab. It was a horrendous exercise… We had to do it to try and build a new system" (Clinical Chemistry participant)
Communication channels	If it is ordered by phone or fax you know straight away, but if it is ordered electronically it will just sit in the 'end list'… (Blood Bank participant) "Do you see us … sitting reading plates and looking up the whole of the patients' clinical notes? (laughter)" (Microbiology participant)

Temporal considerations

The elimination of previous data entry requirements for the laboratories was also associated with a major decrease in the time it took the laboratory to produce a result that was available to clinicians. For the Haematology and Clinical

Chemistry departments timeliness is an essential component of their work and was one of the indicators which they identified as key to judging the impact of the new system (see Table 1).

Both departments are also subject to a complex array of organisational factors and procedures that affect the temporal flow of the laboratory process. For instance, Haematology and Clinical Chemistry are required to service several hospitals across a large metropolitan area. These hospitals have different levels of laboratory capacity. Some periphery hospital laboratories do not carry out coagulant testing while others do so only in urgent cases. The task of ensuring the temporal coordination and efficiency of laboratory work is a major task which involves a processing cycle designed to ensure that specimens are delivered to the appropriate laboratory within the correct timeframe. Failure to do so means that a courier run may be missed and the laboratory is forced to either perform extra work on site or else arrange for special (usually expensive) transportation to ensure delivery of a specimen. Participants reported that it required a major effort to identify and detail these procedures in a flowchart in order to ensure the smooth transfer, to the new electronic ordering system (see Table 1).

Communication channels

In some cases the new system involved a shift from previous synchronous communication channels (eg, telephone calls) to asynchronous channels involving standardised orders and electronic messages, which can represent major challenges for previously existing pathology processes. For the Blood Bank, the asynchronous character of electronic ordering of life-critical blood products was delayed because of department concerns that an asynchronous order may go unnoticed (see Table 1). The Blood Bank concern about asynchronous communication channels contrasted with that of the Microbiology department who were concerned that the new system's ability to improve communication across the laboratory – ward interface should not lead to the transmission of enormous volumes of irrelevant information where a lot of data is transmitted irrespective of its context or value (see Table 1).

Discussion

An organisational and communication perspective

The findings from this study reveal three key themes which have implications for the functioning and organisational dynamics of the pathology service. These include a) work process changes that affect the output of the pathology laboratories; b) temporal considerations, particularly as they related to efficiency of laboratory processes; and c) communication channels and the resulting changes in the mode of information exchange and communication. These categories emerged from a close analysis of the contextual setting of each department, their contrasting and interconnected scientific and organisational tasks and the role they play in the pathology test order process [7]. This process begins with a clinician's decision to issue an order, its collection and passage through the laboratory process and subsequent test result application as depicted in Figure 1.

Pathology services, like those in other parts of organisations, can be defined as vehicles for converting inputs into outputs. What this study shows is that the production of outputs, in this case laboratory test results, involve aspects of information processing, communication and organisation all carried out within a unique temporal framework [10].

Planning, organising and controlling the pathology work environment

The introduction of electronic ordering has important consequences for the work of pathology services and their role in the delivery of healthcare. New technologies like electronic ordering greatly enhance the speed of communication, provide the potential for higher volumes of data to be transferred, and allow the linkage and storage of information across multiple sources [11]. Prior research has shown that whilst this opens up the possibility of significant benefits including efficiency gains, [12] work innovation [13] and greater effectiveness [7], there is also the risk of the unintended consequences leading to the introduction of potentially dysfunctional work practices [6, 14].

Our results showed significant advantages of electronic

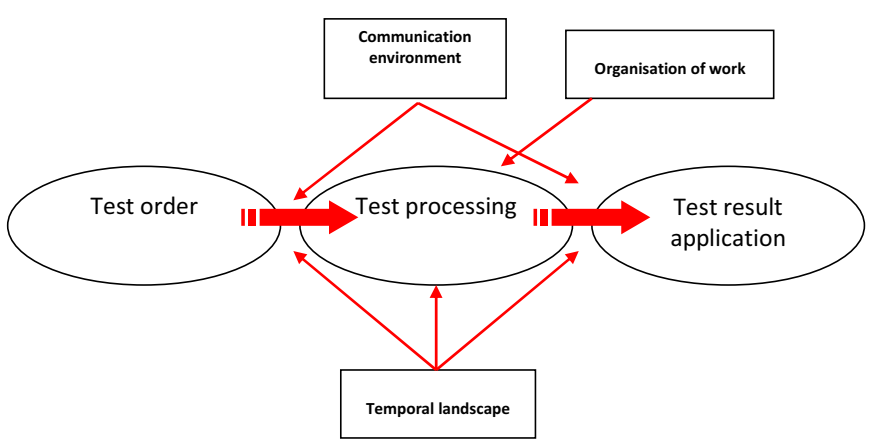

Figure 1 - The organisational, communication and temporal implications of CPOE

ordering leading to improved efficiency (elimination of data entry tasks) and safety (less handwritten errors). However, they also revealed that some features of the new system may lead to unexpected features as in the case of the Blood Bank's concern about a potential failure to be notified of an urgent blood product.

Communication environment

The idea of providing data and information to the right people at the right time and place is a key feature of most new information and communication technologies. However, a case study by Davidson and Chismar of a private, urban, acute care unit using in-depth interviews, showed that the structuring and formalisation of data in electronic ordering systems has the potential to create ambiguity and uncertainty about orders [15]. As the findings of this study highlight, the availability of masses of information to the Microbiology laboratory was not a guarantee of its appropriateness and usability. Information exchange should not neglect the social context which provides information with its meaning and importance [16]. Berg and Goorman assert that data are always produced with a particular purpose, hence their specificity and flexibility should be customised to suit that purpose [17].

The temporal landscape

Organisations are constantly searching for ways to improve their use of time. This is because of the implications that time has for how work is prioritised, allocated and coordinated [18]. Work is organised to suit timeframes that may contain different assumptions and meanings. In this study we witnessed both the concern for ensuring the efficient production of laboratory test results as measured by turnaround times, and the need to fit work into a series of time cycles that impacted on the coordination and synchronisation of work, eg, tests from remote laboratories. Time in the laboratory process can be considered either as a dependent variable (eg, turnaround time) that has been affected by data entry efficiencies introduced by electronic ordering, or alternatively as an independent variable (eg, fitting into existing laboratory procedures) whereby the electronic ordering system is modified to fit the temporal exigencies of the pathology service [19].

Limitations

This study used rich contextual data to examine key features of pathology services and the impact of electronic ordering. Even though the findings are presented in a conceptualised framework their generalisability are likely to be affected by the particular circumstances of other settings.

Conclusion

This study has shown that CPOE can impact upon many features of the pathology service. CPOE implementation should be premised on a solid understanding of the organisational, communication, information and temporal circumstances in which the system is meant to operate [17]. As this study has shown, new technology will affect the organisation of the healthcare facility, but the new technology's fit and usability will also be shaped by how users manage, plan and negotiate its uptake.

Acknowledgements

This study was part of an Australian Research Council Linkage Grant (LP0989144) to evaluate the use of information and communication technologies and their ability to support effective work practice innovation. The authors acknowledge the role of pathology service staff for their participation in this study.

Clinicians, security and information technology support services in practice settings- A pilot study

Juanita Fernando

Mobile Health Research Group, Medicine Nursing and Health Sciences, Monash University, Melbourne, Australia

Abstract

This case study of 9 information technology (IT) support staff in 3 Australian (Victoria) public hospitals juxtaposes their experiences at the user-level of eHealth security in the Natural Hospital Environment with that previously reported by 26 medical, nursing and allied healthcare clinicians. IT support responsibilities comprised the entire hospital, of which clinician eHealth security needs were only part. IT staff believed their support tasks were often fragmented while work responsibilities were hampered by resources shortages. They perceived clinicians as an ongoing security risk to private health information. By comparison clinicians believed IT staff would not adequately support the private and secure application of eHealth for patient care. Preliminary data analysis suggests the tension between these cohorts manifests as an eHealth environment where silos of clinical work are disconnected from silos of IT support work. The discipline-based silos hamper health privacy outcomes. Privacy and security policies, especially those influencing the audit process, will benefit by further research of this phenomenon.

Introduction

This paper analyses feedback from information technology (IT) support staff and clinicians about their perceptions of work with eHealth security implementations in the natural hospital environment (NHE). Key features of the NHE include inadequate infrastructure, pervasive computer use, shared clinical workspace, aural privacy shortcomings, highly interruptive work settings that threaten private and secure (P&S) e-health training outcomes and inadequate budgets [1].

Studies reviewing clinician work with P&S eHealth tools in the NHE began emerging from the 1980s. For the purposes of this paper, the term *eHealth* broadly refers to patient health records stored on computers in care settings. Theorists recognized the potential synergies between clinical work and IT support [2-4]. The studies are among the forerunners of multidisciplinary knowledge about the impact of IT support on clinical work with eHealth. Sociotechnical approaches advance our current understanding of eHealth implementations too [4-9]. Sociotechnical approaches "consider and optimize both the technical work processes and the social systems operating within the work environment to improve organizational performance" [7]. Post and Kagan's (2007) study of security tools trade-offs to maintain productivity furnishes an example of the sociotechnical approach in action [9].

The 2008 study by van der Linden et *al.* reviews P&S issues in the context of interoperable systems architecture emphasizing the need for a paradigm shift from centralised to localised systems to advance P&S patient care[10]. Other important works, such the efforts of Brogan et *al.* (2007), in the context of password security tools, and Williams (2008), who analysed P&S tools in the GP setting, try to understand the end-user experience of eHealth implementations [11,12]. Notably, Pagliari (2007) maintains the common pattern of working in discipline-based silos has supported the development of an IT environment that runs in parallel, rather than harmoniously, with the clinical user environment [2]. The literature suggests understanding the P&S interface between clinicians and IT support staff is a foundation of improving eHealth performance in patient care settings [5]. Hence this pilot work analyses beliefs of IT staff about work with P&S in an eHealth hospital context and contrasts this with the findings from an earlier case study of clinicians in the NHE [1].

Method

IT participants were drawn from a purposive sample of IT staff at public hospitals in Victoria (Australia). "*IT staff*" refers to hospital staff with reporting lines to executive information managers. The participants were recruited from tertiary hospitals in rural, urban and suburban locations. After human ethics clearance, managers passed on recruitment material for the study during regular meetings with groups of staff. Nine IT staff from various departments, as is illustrated in "Table 1. IT participant profile" volunteered to join the study.

Table 1- IT Participant profile

Area	Case	Sex	Title
Urban	1	M	IT Manager
	2	M	IT Manager
Subur-ban	3	M	Clinical Informatics Manager
	4	M	Computer Services Manager
	5	M	Departmental IT Officer
	6	M	Departmental IT Support Officer
Rural	7	F	Health Informatics Services Manager
	8	F	Hospital IT Support
	9	M	Hospital IT Manager

Case study data from the second group of participants, clinicians, has been added to IT data and is re-used for this work. The clinical participants comprised nine medical, eight nursing and nine allied health participants. That study asked about clinician security practices when using health systems for patient care. The participants were drawn from various departments of the same hospitals as IT participants [13]

The sampling and ethics methods for the older work reflected those used for this case study. A lack of available volunteers meant no attempt was made to select participants based on specific clinical or IT disciplines. The data collection factor in common was that all participants worked with P&S eHealth tools for patient care at the Victorian public hospitals. Presumably participants that volunteered for these studies were more interested in P&S than their counterparts.

Both case studies relied on the 'questerview' technique, which asks standardized questions during qualitative data collection [13]. Participant questions were structured, ostensibly to obtain closed answers during interviews, which were tape recorded by the researcher for later qualitative analysis. The juxtaposition of clinician feedback, published earlier, with the new data from IT support staff at the same hospitals compliments our present understanding of work with P&S in eHealth settings.

Results

The results section initially aggregates key feedback from the clinicians. A report of feedback from the IT participants follows. Taken together, the sections summarize all of the key research data underpinning this work.

Clinical evidence

Key clinician feedback is depicted in "Table 2. Summary of the clinicians' evidence" [13]. As the table shows, clinicians were required to share computers at the user-level environment. Queues for access to the computers were frustrating and delayed patient care tasks so that clinicians "sometimes did not bother" updating patient records on eHealth systems at all.

The system environment for eHealth was described as 'sluggish' by participants. Software evidently did not intercommunicate, even when on the same computer. Most applications required a unique logon combination of user-name and password for access to care information enabling clinician access to a single episode of patient care. Computerised access control lists, which tailored an individual's authorisation to eHealth systems by patient consent and work role, were characterized as cumbersome and ineffective. Finally screen-savers asking for a logon combination to continue work interrupted the diagnostic process as well as costing valuable time for patient care. Screensavers blank a monitor when no user activity has been sensed for a period of time. Feedback suggested the system environment was so slow and cumbersome; it often disrupted patient care work.

Table 2- Summary of the clinicians' evidence [14]

Implementation	Manifestation	Result
Shared computers	Queue	Frustration
Slow system	System latency	Disruptive
eHealth applications	Multiple logons	Impractical
Passwords	Fear of lockout	Avoidance
"Handover sheets"	Paper persistence	Collusion
PKI	Inflexible	Collusion
IT Support	Authority	Resignation

Passwords for logon to the eHealth system were also too numerous for participants. One medical clinician explained the range of passwords he needed to remember exceeded one's cognitive capacity. Forced password resets and alphanumeric, mixed-case combinations (e.g. M0n@5h) to enable ostensibly safe user choices exacerbated the shortcomings participants associated with the P&S tool. Further, the clinicians felt the process of obtaining a replacement password, should one be forgotten, was both tedious and frustrating. Fear of system lockout as a consequence of forgetting passwords triggered a range of clinician responses, from the illicit storage of the combination on a computer screen or notice board, to "cheat sheets" in some settings, generic ward logons and avoidance techniques, such as sharing logons. These shared logons often gave greater access to the eHealth system than the clinicians own and so were seen as pragmatic solutions for access to patient care information at all system-levels.

The table also illustrates the clinicians' beliefs that "*handover sheets*", as the clinicians called them, were an "important medical tool*"*. The sheets amalgamate patient information from a range of eHealth systems into a printed document. Sharing user credentials with colleagues allowed written updates from ward rounds to be transcribed by a staff member later in the day. Collusion over eHealth P&S tools for access to productive patient information from "the multiplicity of systems on wards" was a common participant experience.

Public Key Infrastructure (PKI) was apparently inflexible for use in patient care settings. PKI protocols incorporate digital signatures and digital certificates, which are protected by passwords or keys, to decipher encrypted data. The protocol relies on evidence of identity, generally a face-to-face check, conducted by the issuing authority [14]. Several clinicians evinced concern about the effectiveness of the security tool. For instance, PKI authenticates users for eHealth. However if the authenticated clinician leaves the computer without logging out then others might harness the PKI authorisation

for their own purposes. Given the highly interruptive NHE, this scenario often occurred in patient care settings at the hospitals. In some cases the collusion was deliberate, with clinicians often sharing their PKI user details with others during holidays or illness. In other cases, the interruptive nature of clinical work underpinned the breach. The clinicians' believed PKI was no more robust than any other security tool used in patient care settings and, in any case, would increase their dependence on IT departments.

The participants believed IT departments at the hospitals were responsible for most eHealth shortcomings. They were worried by system failure at the hospitals, although could not quantify its frequency. The expression "IT failure" was used to describe all the technical difficulties the clinicians had ever experienced or heard of in the NHE. Preparing for IT failure, one participant backed up her own system storing "paper copies of pretty much everything" on her computer. A staff survey expressing dissatisfaction with clinical IT devices were the substance of a complaint from another but "nothing …happened". Other clinicians believed IT departments "really don't meet the times [sic]". Most clinicians had "simply given up" on IT support because "the process was too much of a hassle".

Evidence from IT staff

This section reports on key data collected for this study about supporting secure clinical work with eHealth. Key themes from interviews with IT staff are summarized in "Table 3. Summary of the IT support feedback". The table illustrates IT staff feedback about personnel and technical resources shortages linked to inadequate budgets. The following comment from one participant epitomises these. He said, "No we can't afford that" in reference to a P&S tool. Another participant explained, "We're only a small team", referring to her department. Still another said, **"**We are so small …I think everywhere bogs in these days … you have to, haven't got much choice". Finally, a fourth IT participant suggested resources shortages meant IT staff were not always trained for the tasks they did. He said, **"**I haven't got teams of specialist people, they're all multi skilled … one of my colleagues did an upgrade yesterday … half past five last night we're ringing him up to find out certain things because the documentation was incomplete". Participants believed IT resources were inadequate to support their hospital communities efficiently.

As Table 3 illustrates, the IT support staff also thought maintaining a secure eHealth clinical setting was demanding. The participants knew their responses were being recorded while talking about clinicians as end-users, yet were very frank throughout questerview. One participant explained, "[eHealth P&S] is very challenging, you've got to drum it into … [users]". Yet another IT participant said "one of the things we've got to do is get security into … [users] … People don't realise that an instant could be all it takes for somebody to try and enter the computer". All IT staff had noticed clinicians using stick-it notes and cheat sheets to store username and logon combinations in patient care settings. Still another IT worker wryly commented "we will tell the business manager the password and they will give it to … [others]". A tangible frustration with the clinicians' priorities permeated the feedback. Yet participants were also resigned to managing eHealth P&S risks in clinical settings. The relationship between IT and the clinicians was sometimes contradictory.

Table 3- Summary of the IT support feedback

Experience	Manifestation	Result
Shortages	Small teams	Technically inefficient
Clinicians	Incomprehension	Resignation
Password administration	P&S tools escalate	Counterpro-ductive
CD, DVD, USB	Locked down	Flash cards
Support structure	Fragmented	Disconnection
Auditor	P&S reports	Key priority

The table also lists passwords as a key P&S concern for IT. All the participants helped to administer "one end-user one logon combination" policies at the hospitals. However complaints from clinical departments sometimes caused policy adaptations such as generic user names (i.e. "Ward 21"), where many clinicians shared a single computer account. One IT participant, summing up her colleagues feedback said, "[In] … certain wards, it's a balancing act between the [P&S implementations and clinicians' patient care work]". Evidently IT work included making pragmatic judgements about the quality of P&S tools for care in the NHE.

Notably, the IT participants, as with the clinicians, spoke about the range of logon combinations required for complete access to a single patient care record. One IT participant explained, "… you only need one username and password for both [hospital] systems. However for security you have to set up an[other] account." Evidence from the IT staff suggests P&S system requirements multiplied the number of logons need for clinician access to eHealth systems.

For the most part IT staff reported locking down Universal Serial Bus (USB) ports and portable media at the hospitals. The USB ports enable portable devices to connect to a computer without restarting it. However other staff explained this was not always the case. One participant said, "every Tom, Dick and Harry uses their USB to take [data] home". It seems even after locking down USB ports and CD or DVD drives at the hospital where he worked "Flash memories come in [sic] and people just walk in and out with the bloody stuff". Flash memories are electronic cards that store data. The feedback suggests that as security controls were implemented at the hospitals, clinicians found ways to avoid them.

Several participants commented on the structure of IT support services at the hospitals. One IT participant explained support responsibilities were fragmented. He said "what I am doing is not complete by itself, for many things I go back to [other IT staff]." He continued "… for any change, there is a Change Manager, we have to go through him personally". Another participant confirmed the feedback. Speaking about requests for IT support, he explained, "you could fix [the job] there and then but there's a procedure … part of that is the security, its

only a subsection of it [sic].” The participant was then called away to organise a major system change, ending the questerview. The reported segregation of many duties apparently ensured IT participants tended to be time-poor and disconnected from each other.

Finally, as Table 3 suggests audit priorities were paramount for the NHE. Feedback indicated IT policies were audited by external health authorities every few years to renew hospital licences. Annual internal audits of the hospitals were outsourced to contractors. The frequency of both types of audit depended upon previous findings.

Most IT participants spoke about policies emerging from audit requirements. The policies forced many of the password practices that the clinicians found cumbersome. These policies included the multitude of numbers required to authenticate eHealth access, forced password resets and alphanumeric password selection. One IT participant described the audit process. He said “… as part of a review, we have to look at everything … we have to present all our documentation to the auditors”. A participant from another hospital agreed. She said “Yes … [the auditors] … come in and interfere sometimes, well … strongly suggest that you adopt, with financial incentives or otherwise with disincentives [sic] [their preferred P&S systems]. The feedback implies that auditors generally relied on paper-based or electronic reports to inform their findings and recommendations. IT Support participants, for seemingly pragmatic reasons, considered audit requirements a higher priority than clinician P&S support tasks in the NHE.

Discussion

Three key themes emerged from this comparison of clinician feedback with that of IT staff at the hospitals. The themes concern eHealth resources, the functionality of several P&S tools and evidence of tension between both groups of participants.

Resources

Comments made by both clinician and IT participants illustrate the point made by Post and Kagan (2007), who argue organisations rarely deliver the increased IT support required to adequately underpin P&S implementations[10]. IT resource constraints, such as an inadequate number of computers and associated access queues, eHealth applications that didn’t interoperate and multiple logons for a coherent view of patient information frustrated the clinicians. As a result, some clinicians did not always update patient care records.

IT participants consistently referred to shortages of technical resources and skilled staff. These participants explained the IT teams were, by necessity, multi-skilled in a practical sense if not by certification. IT teams were time-poor due to their small size and the breadth of their responsibilities in the NHE.

The combined experiences of both cohorts are worrisome. The feedback suggests care information stored on eHealth systems may not be reliable for patient care. Auditors provided financial incentives to decide on P&S policies. The time-poor IT teams comprised a resource shared by clinicians, as well as other sections of hospital communities at the sites. The consequence of these experiences may be three-fold. Firstly, eHealth systems are likely to hold unreliable data. Secondly, unreliable data can foster adverse health affects (AHEs) for patients. Finally, the P&S tools utilized for access to eHealth were not tailored to contextual clinical needs. These findings suggest health authorities should review access to resources in the NHE to address the P&S issues emerging from questerview evidence.

Usability

The evidence indicates that clinicians did not find the eHealth system usable. “*Usability”* is a term describing the ease with which users can interact with a computer system. The clinicians believed the system was slow, clumsy and ineffective, or even worse, interrupted the diagnostic process. Applications on the same computer frequently could not communicate with each other let alone networked computers. The participants believed P&S tools for eHealth, such as logon combinations, were both onerous and numerous.

The clinicians’ widespread fear of system lockout due to forgetting one’s password resulted in the eHealth avoidance techniques, as Post & Kagan suggest [10]. The questerview evidence suggests these techniques included the illicit storage and publication of logon combinations, collusion over user credentials and the use of handover sheets, which were based on transcribed data, to provide patient care. Transcribed notes have long been associated with mistakes that cause AHEs[14]. The clinicians saw no point in PKI implementations in care settings due to their interruptive work flow. Frustrated by disruptive eHealth tools, the clinicians tended to believe IT services were at least partly responsible for their lack of control over the storage of patient care information.

Audit

IT staff feedback suggests many eHealth P&S tools made the clinicians’ concerns difficult to address. Hospital eHealth systems did not require multiple logons but P&S controls did. The P&S controls were required to pass regular system audits underpinning hospital licenses.

It seems audits, some contracted internally, generally reviewed eHealth P&S policy documentation and system processes. IT participants explained audit reviews did not extend to actual user environments. Local audits were evidently triggered by actual security incidents occurring between the hospital audits. Once effective controls to the local threat had been developed, they were incorporated into policy documents for the next audit.

The external audit process has much to commend it. The process addressed conflict of interest concerns at the hospitals. Also, system concerns were incrementally controlled as they arose and were looped back into hospital policy for future audits. Yet feedback from both groups of participants suggests a gap in the crisis management audit approach – the patient care setting. The feedback shows clinicians habitually addressed their own eHealth concerns in isolation from IT. It is reasonable to assume this habit resulted in relatively few

crises, limited IT support, and so solutions were rarely incorporated into hospital audit policies. As a consequence, unless thoroughly reviewed, audit processes may prove irrelevant to numbers of AHEs or threats to the P&S of eHealth systems.

Tension

The relationship between IT staff and clinicians was tense. The evidence indicates the clinicians believed eHealth systems were unreliable and controlled their access to patient care information. P&S trade-offs, such as shared passwords, allowed the clinicians to avoid using eHealth systems and so minimised the need for IT support. The cohorts evinced frustration with each other throughout the questerviews.

IT support staff believed achieving P&S eHealth systems in end-user environments was challenging. For instance directives to lock down removable media, such as USB ports, were corrupted by end-users carrying flash memory cards. Logon combinations were commonly stored on stick-it notes and displayed at the hospitals too. The IT staff felt they needed to "drum" P&S eHealth practices into the clinicians.

A clear contradiction between clinician and the IT work goals emerged from questerview evidence. IT tools disrupted patient care work, potentially fostering AHEs. So these were often thwarted by clinicians at the hospitals. The IT staff were both frustrated by clinicians and, by contrast, were also resigned to clinician P&S practices. Evidence suggests the participants were locked into disciplinary silos.

These findings support Pagliari's (2007) reflection about parallel clinician and IT work practices [2]. Participants did not acknowledge their differing motives and operational constraints. Thus the contribution of further research trying to understand or develop active collaboration between clinicians and IT support will advance P&S concerns. The collaborations may also reduce the number of AHEs associated with poor eHealth implementations.

Conclusion

This work compares the approach of IT support staff and with that of clinical staff to eHealth as it relates to the P&S of patient care data to show that neither cohort felt they could control P&S at the hospitals. Their evidence suggests resources shortages combined with clinician avoidance of eHealth manifested as tension between both cohorts of health workers. Further research is needed to understand the undoubted impact of resource shortages, usability and tension between IT and clinicians on effective eHealth implementations.

Acknowledgment

I am grateful to the reviewers for their contribution to this paper.

Abstract

This paper reports a study undertaken in the UK to gather lessons learned from hospital sites that have implemented electronic prescribing systems. The work was commissioned by NHS Connecting for Health, the UK Department of Health agency responsible for the implementation of the National Programme for Information Technology. The aim was to capture front-line experience of the project and systems implementation, and to share it with staff who will in the future participate in other implementations. Data were drawn from detailed interviews with staff and a survey in 13 hospitals in England, as well as a review of published studies of implementations. The study output is a report and six user-facing briefing documents targeted at key stakeholder groups; nurses, pharmacist, doctors, senior executives, implementation team members and IM&T staff.

Keywords:

Electronic prescribing, Implementation, Evaluation research, Lessons learned.

Introduction

Prescribing and administering medicines is a core activity in modern medicine. Doing it intelligently and safely is one of the most significant measures of the quality of the care that patients receive. Maintaining and managing information about drugs prescribed, dispensed and used is a significant element of a patient's medical record which itself underpins good care at the point of delivery. For the managers of health care systems, from the ward or clinic up to the national level, knowing about how medicines are used is important for pinpointing areas for improvement, managing budgets and reacting to new circumstances. Electronic prescribing (eP) systems, found increasingly in both primary and secondary care settings, can support the delivery of care and the management of health care systems.

However, the level of implementation and use of electronic prescribing systems does not seem to match the potential they seem to offer and despite the substantial research evidence for their beneficial outcomes, and many official endorsements of electronic prescribing systems as a core clinical technology, it is still that case that not very many hospitals in the UK or other countries have achieved comprehensive systems in hospital-wide use. There are of course some notable exceptions and, for example, the Royal Hampshire County Hospital, Winchester in the UK became probably the first hospital in Europe to replace one eP system that had been in use for over 10 years with another. Still, the implementation of ePrescribing (eP) in acute care in the UK has been limited to a small though growing number of sites. This is in direct contrast to primary care in the UK where computer prepared prescriptions are now the norm and the electronic transmission of prescriptions from general practitioners to high street pharmacies is in use and being upgraded in England to a service with electronic repeats and full electronic signatures under the Electronic Prescription Service[1].

Existing secondary care implementations in the UK include some that have developed out of specialist clinical needs and may be localised to a single ward, (ICU, oncology, renal), some out of pharmacy systems, and some as part of a wider implementation of hospital information systems. In prospect for all hospitals are electronic prescribing modules as a part of large whole hospital electronic patient record (EPR) systems to be implemented under NPfIT, as well as more implementations of specific eP systems.

The relatively modest scale of electronic prescribing in the UK acute care setting might be explained by a number of factors. These include a perception that electronic prescribing is technically difficult and challenging, that available systems are not sufficiently well developed to deliver benefit, that other sibling systems need to be in place *before* electronic prescribing is rolled out, or that the culture change required for adoption into clinical practice is too hard to achieve. The proposed roll-out of EPR under NPfIT has suffered many delays and may have caused some 'planning blight' making it harder to secure a budget for separate eP implementations.

The work reported here was commissioned by NHS Connecting for Health, the UK Department of Health agency responsi-

ble for the implementation of the National Programme for Information Technology. The work addressed some of these impediments by synthesizing the lessons learned by staff in hospitals that had implemented electronic prescribing, and passing them on to other front line staff and managers. The aim of this study was then to help build confidence among such staff that hospital-wide electronic prescribing was achievable, and to help people to prepare for the implementation of such systems.

This study is in this respect rather different from most evaluations undertaken in health care, having as its objective a focus on the processes of implementation themselves, seeking an *emic* account, rather than a focus on outcomes of an intervention *per se*. Further, the main audience for the work was intended to be the peers of those reporting their experiences from within the hospital culture, rather than policy makers, senior managers or technical staffs.

Study background

The systems used for prescribing inpatients medications and recording administration in UK hospital are based on a model established in the 1960s. Doctors write medication orders directly onto a paper drug chart or medication Kardex, and the same document is used by nurses to find out the doses due and record administration to the patient. The drug chart is also used by pharmacists to clinically screen and supply medication, as well as by other healthcare professionals when they need to view a patient's current medication. The single document has great advantages in that everybody looks at the same version of information, but there are some known problems with this system. UK studies show that:

- prescribing errors occur in 1.5-9.2% of medication orders written for hospital inpatients [2-6]
- dispensing errors are identified in 0.02% of dispensed items [7-8]
- medication administration errors occur in 3.0-8.0% of non-intravenous doses [3, 9-11] and about 50% of all intravenous doses.[12-13] (These figures exclude errors involving wrong time of administration).

In the past decade there have been a number of significant changes in the ways in which medicines are used in secondary care [17]. For example, prescribing roles have expanded to include nurse and pharmacist prescribers, the use of patients own drugs (POD) help to manage waste and to allow patients more participation in the processes of medicines use. More attention is now focused on the consequence of adverse drug events (ADE), where the medicine use process breaks down, and patients suffer, as when allergy information is not sought or is not used or when prescribing data is unclear, incomplete or in error. Various estimates have been made as to the cost of such errors, and while the exact detail may be disputed, the overall impact of ADEs is clearly significant.

Against this background, and drawing in particular on the concern with preventing errors, there has developed a strong movement that advocates using the computers to help deliver new means of managing drugs. Influential reports from the U.K, USA and other countries have suggested that computerised medicines management should become an essential part of modern medical practice[14-17] Such systems are discussed under various names. In the United States the most common name used has been the abbreviation CPOE, though its exact definition has shifted from 'Computerised Physician Order Entry', to 'Computerised Provider Order Entry', in line with the expansion of prescribing authority. In the UK the term CPOE has not been so commonly used since UK practice in hospitals has been to separate the orders for drugs from other medical orders such as physical therapy, tests or imaging. It is more common in the UK to speak about electronic prescribing systems, abbreviated to eP, and to separate them from systems that support other types of clinical orders. NHS Connecting for Health's formal definition of ePrescribing is as follows:

> The utilisation of electronic systems to facilitate and enhance the communication of a prescription or medicine order, aiding the choice, administration and supply of a medicine through knowledge and decision support and providing a robust audit trail for the entire medicines use process [18]

Thus the phrase 'electronic prescribing' should not be taken to indicate that the only purpose is to help in prescribing activity. Prescribing is of course an important aspect of eP systems, and the use of decision support for prescribers, alerts for allergies or drug-drug interactions, or order sets, can offer significant improvements in care. But contemporary eP systems serve wider purposes in prescribing, supply, administration and recording functions, as well as audit and review. Indeed it is exactly *because* such systems can integrate these distinct activities that they are seen as useful and able to contribute to improved patient care. For example, if a drug is prescribed, and the eP system knows that it is not currently on the ward in sufficient quantity, an eP system may be able to generate a supply order in the pharmacy.

Materials and Methods

The objectives of this study were: to accumulate and summarise the varied experiences of NHS hospitals in the UK as they have implemented (or failed to implement) various versions and styles of electronic prescribing (eP), to review relevant international literature on the implementation of eP, commenting on the messages that can, and cannot, be extrapolated to the UK, and to develop a set of short and informative practitioner facing briefs that address key aspect of eP.

Data were collected by interview, through a detailed questionnaire for key personnel from eP sites, and by review of published materials. The work drew on the input from over 50 staff in 13 NHS hospital trusts, representing the implementation of 20 different systems.

The study resulted in a report but given its aims other important outputs were six user facing briefing documents (leaflets) targeted at key stakeholder groups; nurses, pharmacist, doctors, senior hospital executives, implementation team members and IM&T staff. These outputs form the basis of a toolkit including a PowerPoint presentation that can be adapted for use

in a variety of settings. The final results can be found online [19].

Results

Of course, not all people reported the same experiences, and sometimes the reported 'Lessons Learned' were contradictory. However, most often people who had experienced eP implementations told a similar story, and seemed to draw similar conclusions. Given that the focus of the study was on implementations of sophisticated IT systems we found, as expected, a number of well established themes that are associated with implementing any type of information system in a health care setting. For example, most people expressed the need for senior managers' support from the initiation of an eP project and throughout its progress, emphasised the role of champions, the importance of user involvement and the need for (and problems achieving) 'clinical engagement'.

These are undoubted necessary conditions for a successful eP project. However, there are also some subtleties that need to be added, placed within a discussion of the specifics of the implementation of eP. We explore here the critical and context-specific themes that emerged as making eP projects different or distinct, and which can help to identify specific actions and attitudes needed. Thus we reflect here an experiential, 'bottom-up', view – eP as seen by the main stakeholder groups that have to absorb the new technology and release its benefits as they develop their own new ways of working.

Getting Started

Many of our respondents had been involved from the start of their hospital's eP project. Their views, with the benefit of hindsight, were often that the 'vision' of eP needed to be established and communicated first, both in terms of the big picture (patient safety, modernisation, e-health strategy, eP's role as an innovative clinical system), but also in terms of the significant details that would shape the eP system in that particular hospital's context. Such details include identifying the benefits that eP offers to the multiple stakeholders. Is there something positive for everybody? Where are the most receptive parts of the hospital? Which specialties can be relied upon to embrace eP with enthusiasm? Which ones, once convinced, will carry the message loudest? And which ones will be most problematic?

An almost universal finding from our respondents was that eP projects must be multi-disciplinary. No one professional group can carry a successful system into widespread use. If significant professional groups are missing, excluded or unenthusiastic, then this is storing up problems ahead. As one project lead said; "Undertake lots of visits and talks, if need be grovel, go everywhere and sponsor events. Do everything to build up visibility." Many of our respondents reported a desire for more clinical participation at the outset, in particular from doctors, but they also noted the importance of support from IM&T members who really understand what is being demanded. Management backing is vital too. eP projects, inevitably raise some resistance, perhaps quite a lot from some clinical quarters. If senior managers are other than fully committed, then eP projects may be wounded or even fatally challenged. Of course, to attain the backing (and sufficient budget) from senior management requires that they are well briefed and confident both of the eP team's ability both to effect the implementation and then to deliver real benefits.

One responded advised; "If possible implement X-ray and lab test ordering before EP: this helps users realise the benefits of electronic orders". This may not be a feasible recommendation in some situations, however, the wider point is valuable –eP is best seen as part of a broader programme of implementation of innovative clinical information systems, and success in one area can reinforce success in others.

The Build up

Successful eP implementations are not just multi-disciplinary in their project team, but also reach out across the range of healthcare professionals both to communicate the benefits of eP and to bring out into the open any fears, concerns or areas in which eP may be problematic.

Planning the implementation of eP requires quite careful reconnaissance. Identifying people who can support and develop eP is important: people who can deal with information and communication technology, are happy to change the way they work, and who can enthuse and support others. Of course, not everybody falls into this category, and almost all sites studied had their stories of resistance. Nevertheless, a successful eP implementation can go ahead.

The respondents had learned from experience that eP is less easy to incorporate in some clinical specialities, and that some drugs have specific regimens that challenge the simple logic of most eP systems. For example, paediatric prescribing raises many distinctive problems; A&E work practices may require that prescribing be undertaken in different ways – e.g. using patient group directions (PGDs). And medicines such as insulin, warfarin or heparins each pose problems of how exactly they should be incorporated into eP procedures. Many eP systems struggle with these and other medicine's variable dosing, and often some paper charts must be retained. The eP system then needs to reference these paper charts and incorporate key information such as administration schedule.

In addressing such tricky problems, and thinking through the ways in which to safely accommodate them in eP, broader confidence can be built up. Certainly the early adopting eP sites had faced these problems and found acceptable solutions that work for them.

It may be surprising, but the most common 'lesson learned', and sometimes learned the hard way, was that hardware and software can be a problem! In particular, a number of the sites studied had significant problems with their wireless networks. These manifest themselves in terms of 'dead spots' where no network coverage is available, or underspecified networks that could not cope with the volume of traffic once substantial amounts of prescribing transactions were taking place. These kinds of problems are particularly troublesome and difficult as they had in more than one case meant having to withdraw an eP system when it had already been established on several

wards. Such problems also emphasised the need for a sound back-up plans so a system can fail safely, and be restarted safely too.

Building a good relationship with software and database suppliers was seen as important. In the early set-up phase of an eP project interactions with suppliers can help to solve problems, and tap into other sites with previous experience of the same software. That said, in order to take ownership of the system, and make it fit into the specific context, staff did need to work on configuring the software and making it look and feel appropriate for *their* needs. This work takes time, and some may be optional ahead of roll-out. That is, a basic system might be rolled out sooner, and extra functionality added to it as time goes by. However, in order to provide the most positive experience of eP to new users providing a rich set of features in the initial roll-out may be important.

Training people to use eP was essential. However, opinions differed somewhat as to how much training is needed and the extent to which it should be on the job or in the classroom. Classroom training was reported as being useful but only if the classroom is suitable with equipment and software that is the same as in use on wards. The counter argument some people made was that if a system is sensibly designed, and if staff have sufficient IT skills, perhaps from other clinical systems, then the training needed should be minimal – just training to deal with site-specific elements such as logons, passwords etc. But training has other roles than just imparting information. It can build up confidence, reveal concerns or pick up important bugs or problems with a system. For this reason trainers were seen an essential element of the eP team – not just teaching the system, but also feeding back changes to make it safer and easier to use. Thus the training role can extend well beyond the initial roll-out and sites with a hospital wide system in use maintained a fully staffed training team throughout the systems working life because new staff arrive, locums can appear late at night and at weekends, new upgrades of software are made, systems are improved and changed, and people may need refresher training or training for new roles.

Implementation and use

Those who had implemented eP across a hospital were almost universal in their view that, once a system has been set-up and tested in one chosen area – perhaps one or two wards with particularly supportive staff - then the full implementation should proceed quite fast. Two reasons are proposed for this. First having two systems (paper and eP) in use in the same hospital makes a lot of work when patients cross these boundaries, and second because it is as a result less safe. In any case, almost all sites studied acknowledged the need for dedicated staff to support eP going live in each location, converting medications orders from the old to the new system, providing on the job training and support, and picking up other nursing tasks as ward staff take time to learn to use eP. A number of sites had used locum pharmacists and extra nurses to bolster the staffing levels during eP implementation. One suggestion from an experienced site was by agreement to draw staff from other local hospitals during the key change-over period. In this way experienced people are available, and mutual learning can occur. This might be even more useful if local hospitals are on track to use the same or similar software in their eP plans.

Reported experience of initial use of eP was of a period of intense activity and support, with mixed reactions by clinical staff, followed perhaps after 2 or 3 months by a more positive feeling, and after 6 months by a feeling of "I would not want to work without eP". Nevertheless, support activity continues to be needed. Indeed it is needed throughout the life of an eP system since problems will keep on emerging as well as new ideas for improvements and new understandings of the possibilities. For example, in the early stages of eP use clinical staff are unlikely to think about the management potential of the data held by the eP system. But a year later, when available data is substantial and covers a period of time, reporting, trend analysis or safety audits may be attractive options. Trainers or other designated people also still need to pick up peoples' concerns and suggestions, and then do something with them. An active and positive support system that feeds back progress on fixing bugs, implementing new features or just answering question is an important part of sustaining eP, and the basis for obtaining full benefits.

eP support is an important task that demands a mix of skills, some IT related, some clinical, and some specific to pharmacy. How to set up and staff such a support operation is not straightforward, and things will not work well if technical questions go to clinical staff or vice versa. eP sites solved this problem in different ways, but perhaps the most successful was to designate a team approach with clinical and technical staff working together.

Using eP has consequences, intended and emergent. Some of these are directly related to the benefits that they offer. For example clear, legible and complete medicines orders mean that pharmacists need to spend less time making simple corrections, they may also spend less time supporting the supply of medicines. On the other hand the work involved in supporting the eP system – keeping it up to date, improving usability, implementing prescribing policies etc, will probably eat up, and may well exceed (depending on Pharmacy's role) the time savings created elsewhere. This may also lead to some consequential changes. For example if TTO (discharge) orders are sent direct to the pharmacy, then expectations will be that they are processed immediately. Meeting such enhanced expectations may not be easy. eP was reported as having consequences for staffing policy too. For example, agency nurses or locum doctors that have not been trained to use a system are less useful. A number of eP sites explained that they had become more concerned to build up a bank of part-timers who were trained, had passwords, and could use the eP system directly.

Conclusions

Our respondents involved in eP implementation in NHS hospitals shared many common insights - different sites often yielded very similar 'lessons learned'. Unsurprisingly, traditional project success factors were as relevant to eP as to any other area of IT, requiring senior management backing, good

project management and user commitment. In particular, in establishing an eP project it was seen as essential to pay attention to building the supporting network. Champions needed to be found and encouraged, and the strong backing of senior mangers obtained. Often, as reported, it is the technology and infrastructure that proved to be the weakest link. These need close attention from the earliest days. And IM&T staff must understand the scale of what is being attempted and the key safety concerns.

It was also recognised that it is important to 'sell' eP's benefits widely, but also early on to flush out potential problem areas and people with doubts. Respondents emphasized the importance of communicating clearly that eP is a major clinical system and demands that everyone involved is prepared to leran new things and change the way they work.

Overall, the key messages that were reported to us can be summarised as follows; build a multi-professional team, plan for early success and to build momentum.; maintain substantial resources to manage develop and grow the system in use.

Acknowledgments

We would like to than the many busy people, doctors, nurses, pharmacists, systems developers and managers who gave us their time and talked about their experiences. We would also like to thank a number of international experts in electronic prescribing who gave us input into the study. The CMSSQ is affiliated to the Imperial Centre for Patient Safety and Service Quality, which is funded by the NIHR

Implementation, monitoring and utilization of an integrated Hospital Information System – lessons from a case study

Ricardo João Cruz-Correia

CINTESIS, Al. Prof. Hernani, 4200 Porto, Portugal

Abstract

In most hospitals several heterogeneous Information Systems (IS) store parts of a still scattered patient record. Virtual Patient Records (VPR) are systems that aggregate known data elements about the patient from different IS in real-time. This papers aims to present the main lessons learned from the implementation and the usage during 6 years of a VPR system. Ten major lessons were divided in recommendations for software developers, information managers and institutional policy makers. Implementing and using a VPR is a difficult journey but can generate great value for the institution if most of these recommendations are taken in consideration.

Keywords:

Hospital Information Systems, Computerized Medical Records Systems, Integration of Information Systems

Introduction

Healthcare is information and knowledge driven. Good healthcare depends on taking decisions at the right time and place, according to the right patient data and applicable knowledge [1].

Patient data is more recorded now than ever before. Communication is of most relevance in today's healthcare settings, as health related activities, such as delivery of care, research and management depend on information sharing and teamwork [2]. Clinical care increasingly requires healthcare professionals to access patient record information that may be distributed across multiple sites, held in a variety of paper and electronic formats, and represented as mixtures of narrative, structured, coded and multimedia entries [3].

In hospitals, information technologies tend to combine different modules or sub-systems, resulting in the coexistence of several IS aiming at a best-of-breed approach. The integration of these IS is essential to support shared care and is a step towards full system interoperability. However, to integrate clinical ISs in a way that will improve communication and data use for healthcare delivery, research and management, many different issues must be addressed [4-6].

Many distinct technological solutions coexist to integrate patient data, using differing standards and data architectures which may difficult further interoperability [7]. Virtual Patient Records (VPR) are systems that aggregate known data elements about the patient from different IS in real-time.

This papers aims to present the main lessons learned from the implementation, monitoring and utilization during 6 years of a VPR system in a 1300 bed university hospital.

Methods

System architecture

A VPR was designed and implemented at Hospital S. João, aiming at delivering, at any point of care, an integrated view of patient data held in heterogeneous IS by retrieving clinical documents and linking federated databases. It is composed by a web-interface (VIZ), an integration system and a central repository (CRep) [8].

The web-interface was designed to include graphical components and layouts to summarise past patient data (patient chronological bars), and folders that reproduce the traditional types of patient record organisations (source, chronological and problem views). It allows ubiquitous access to heterogeneous data sources.

The integration system includes: (a) direct access to legacy databases; (b) a multi-agent based platform acting as the integration engine that ensures the communication between the various departmental information systems (DIS) and the central repository by retrieving and storing the clinical documents; (c) web-services to allow clinical data access by third party ISs; and (d) patient information viewing components to be integrated in DISs.

The central repository holds all integrated patient documents and the document version control files. It enables fast document access by implementing a hashing function to maximise the distribution of patients by directories.

Figure 1 illustrates the main features of the VPR system, namely the collection, verification, encryption, storage and presentation of the clinical documents. The final users, instead

of having to search patient reports on several different IS, use a single interface to perform that task.

System usage

Repository

The VPR has been working since 2004, regularly scanning eleven DISs and collecting an average of 3,000 new reports a day (currently it holds more than 3 million documents).

Security

To ensure confidentiality of the collected patient information the mechanisms implemented were: (a) role-based access control; (b) logging of user actions in VPR; and (c) secure communications using HTTPS protocol [9]. Sharing of logins and passwords between users has been found in 9.7% of distinct logins, which is lower than two other studied EPRs (10.5% and 22.3%) [10]. Although the role-based access control is a powerful tool, Hospital organisational issues limited its use.

To ensure the integrity of patient information the mechanisms implemented were: (a) an algorithm to detect patients' identification inconsistencies between ISs; (b) digital signing and checking for all clinical reports [11]. Patient identification errors have been detected over the years (25, 17 and 18 in 2005, 2006 and 2007 respectively).

To ensure system availability sensors were implemented to detect: (a) DISs unavailability; and (b) abnormal numbers of clinical records retrieved from each DIS. In 2005, 53 abnormal cases were detected corresponding to 44 real problems. The total VPR downtime in the last three years is approximately one hour.

Information usage

A visualization module for the VPR was made available in October 2004. The VPR has wide acceptance and growing usage among hospital health professionals (the number of users increased 29% in 2006 and 41% in 2007 up to more than 1,100 users).

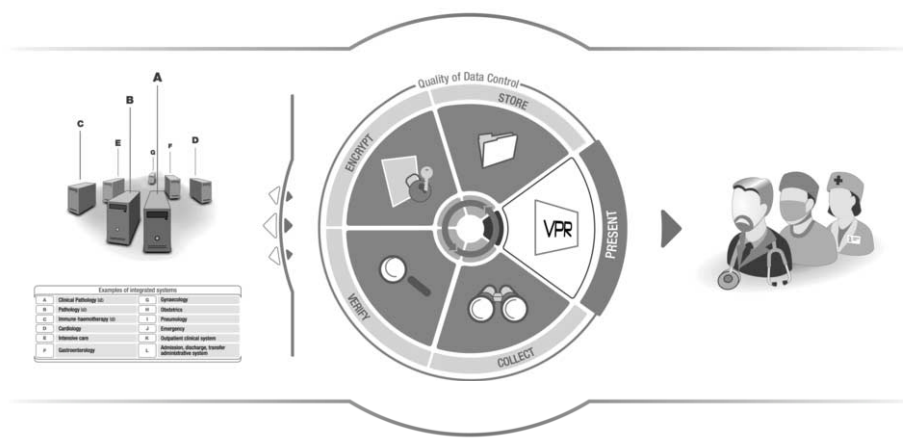
Past information of patients (data from previous hospital encounters) is still used by doctors in new encounters namely those in emergency room attendance (e.g. 52% of the reports viewed in emergency encounters were produced in previous encounters) [12]. The usage of patients' past information is correlated to the setting of healthcare (the half-life of information in documents is 1.5 days for emergency, 4.8 days for inpatient and 37.8 days for outpatient encounters) and to the content of reports (the half-life of immune-haemotherapy reports is 7 days, pneumology 26 days and anatomical pathology is 118 days). The main diagnosis of inpatient encounter is also related with half-life of information produced (e.g. the half-life of reports produced inpatient encounters with neoplasms as main diagnosis is 36 days and with injury and poisoning diagnosis is 17 hours). All these seem important factors to estimate future report relevance.

Discussion

The case study project presented in this paper resulted in the following main findings:

- Different models of integration (e.g. direct database linkage, web-services, and multi-agent systems) had to be used for effectively respond to the integration challenges. If these models are carefully adapted to each situation constrains (e.g. existing physical resources and providers know-how) then little stress is applied

Figure 1 - Architecture of the VPR system implemented



on each integration actor (hospital and several IS providers), which helps achieving proper solutions more efficiently.

- Multi-agent technologies proved to be a robust technology when operating for several years in a large Hospital. They were flexible enough to be used in a highly heterogeneous environment. Multi-agent technologies are suitable to solve complex data integration and communication problems in healthcare institutions.
- The integration of IS raised new security problems (e.g. clinical document version control), and allowed the detection of some previously hidden problems (e.g. time synchronization among servers). Our experience showed that integration could be used to make healthcare institutions take a step forward in the direction of delivering safer healthcare to patients.
- Although role-based access control tools were made available to the Hospital several years ago, the definition of groups and their roles is still practically inexistent. Also, sharing of logins and passwords among healthcare professionals was found to be significant. Defining access control in integrated healthcare environments is a much greater challenge on the organisational and cultural level than on the technical level.
- The dynamic monitoring sensors developed for the VPR that take in consideration the previous behaviour of healthcare professionals and IS, allowed a monitoring that increases both specificity and sensibility. Creating self-adjustable monitoring mechanisms allows effective management in a highly dynamic context.
- Automatically crosschecking patient data (e.g. patient identification) between different IS was an efficient way for the VPR to detect relevant data inconsistencies in all integrated IS. All information available in hospital information systems can and should be used to trigger alerts of malfunctions and inconsistencies, in order to improve patient safety, data quality and ensure a better healthcare.
- Major difficulties were found in the interpretation, data quality and maintenance in using already existing data dictionaries (e.g. patient, professionals or department identifiers). Most of these dictionaries are held mainly by IS suppliers. Healthcare institutions should have a close control on these dictionaries and re-use them in their installed IS; these dictionaries are core elements both in the interpretation of data and system interoperability.
- The usage of past patient information in the VPR case study varies significantly according to patient age, type of information, type of hospital encounter and medical cause (main diagnosis) for the encounter. As more and more patient information is stored, it is very important to efficiently select which one is more likely to be useful and promote it in a scenario where scarcity of resources (screen space, storage space, bandwidth and doctors' time) is very real.

Recommendations

Based on the previous findings, ten main recommendations when dealing with the implementation, monitoring and utilization of an integrated Hospital Information System were created. These were divided in three groups according to the role of person in the organization.

For software developers

1. to seek to comprehensibly integrate all existing IS by making use of different integration technologies;
2. to take in consideration that major differences in maturity exist among the different actors (hospital IT departments and IT suppliers);
3. to consider multi-agent systems when designing integration systems that operate in complex environments like large healthcare institutions;
4. to create user interfaces and data repositories that automatically adapt their behavior to how actually the users work with the IS;

For information managers

1. to create tools that continuously check the integrity of patient data among all IS;
2. to create self-adjustable monitoring sensors for each component of the IS;

For institutional policy makers

1. to allow health information systems to grow both within and beyond the institutional boundaries through integration aiming at semantic operability – *the whole is greater than the sum of its parts*;
2. to regard IS integration as a course to achieve a higher state of information and knowledge use;
3. to clearly define and test confidentiality policies before they are incorporated in IS;
4. to create processes that allow healthcare institutions to maintain their own dictionaries and terminologies of data used in all IS.

Conclusion

The lessons learned and the recommendations are the result of several years on practical experience in installing, maintaining and using a hospital wide integration IS. In the author's opinion, these practical recommendations are useful for most integration projects occurring inside healthcare institutions. These recommendations both can avoid some very difficult problems (e.g. maintaining multiple dictionaries on the same subject), and enable added value to the IS and healthcare institutions (e.g. improving the quality of patient data).

Model-Driven Traceability in Healthcare Information Systems Development

Ståle Walderhaug[a,b], Gunnar Hartvigsen[b], Erlend Stav[a]

Abstract

To improve the quality of software used in healthcare information systems, traceability can play an important role. The concept of traceability establishes explicit trace links in the design, development and maintenance processes, keeping documentation complete and updated. Trace information allows validating bodies, domain experts, system designers and programmers to easily navigate along artefact dependencies and perform simple traceability analysis such as coverage and change impact. This paper presents a novel solution for traceability applied in model-driven development for services in a distributed healthcare environment. The results demonstrate the feasibility of explicitly modelling dependencies using a formal language such as UML. Based on the experience from implementing two full-scale homecare systems in the EU-IST MPOWER project, the potential improvements and challenges with a traceability solution are discussed.

Continuity of care, Service oriented architecture, Model-driven development, MDA, UML, Homecare

Introduction

The software developed for use in healthcare systems should not fail during execution, and ideally, it should have no errors or flaws. However, testing can only reveal errors and not guarantee flawlessness. Organisations such as the Food and Drug Administration (FDA) require a strict validation process before approving software for use with medical devices. Factors such as documentation of the software itself and the development process become important in the validation and testing of software. In [1], FDA describes some general validation principles that they consider important for the validation process. A core principle is related to traceability: "A traceability analysis should be conducted to verify that the software design implements all of the software requirements" (page 19). Furthermore, it states that "a source code traceability analysis should be conducted and documented to verify that: each element of the software design specification has been implemented in code; modules and functions implemented in code can be traced back to an element in the software design specification and to the risk analysis;"(page 21).

Traceability is a concept where the relationships between system artefacts are explicitly described to become a part of documentation, as well as direct input to software development phases and system analysis. With the advances of model-driven software development, traceability has evolved into a concept that includes all system artefacts, from initial mission documents, through requirements, design, tests, deployments, and to operational system versions. Traceability can be used for trace link navigation, coverage, orphan and change impact analysis [2], also know as the core traceability services.

Studies have shown that traceability is considered useful and may have a positive impact on development and maintenance of software [3]. During development and maintenance work, readily access to information about which features that are implemented, why (rationale) and which dependencies that exist between different features and components, is vital for correct (valid) implementation. Arisholm et al have found that "for complex tasks and past a certain learning curve, the availability of UML documentation may result in significant improvements in the functional correctness of changes as well as the quality of their design. However, there does not seem to be any saving of time." [4]

To explore how a traceability solution can be implemented within today's development paradigm, the EU-IST MPOWER project[1] has designed a traceability enabled model-driven development methodology and applied it in development of 25 healthcare specific software services. This paper presents the traceability methodology and results focusing on the core traceability services. Using Unified Modeling Language (UML) [5] as the main notation for domain modelling, requirements modelling, system design and system development, explicit traceability links were created and used for dependency navigation and analysis. Based on the experience from the development project, an extended traceability solution is discussed.

Methods and materials

Development methodology

As described in [6], the developers in the MPOWER project applied a model-driven development approach where *user*

[1] http://www.mpower-project.eu

scenarios developed by *domain stakeholders* (dementia experts, patients, patients' family and caregivers) were incorporated into a UML model for software *service* designs. A total of 137 stakeholders were involved in the requirements development phase: 62 senior citizens (22 in Netherlands, 40 in Poland); 11 Family carers of persons with dementia (5 in Austria, 6 in Norway); 49 Healthcare professionals (all in Poland); and, 15 Dementia experts (4 in Austria, 11 in Norway). The 18 scenarios (2-pages each) constitute the requirements in the domain needs, and is main input to the software service development process. In accordance with the SOA4HL7 Methodology [7], recommendations in [8] and OMG's Model Driven Architecture (MDA) [9], a complete service development process was designed as shown in Figure 1. The development is structured into the three MDA phases.

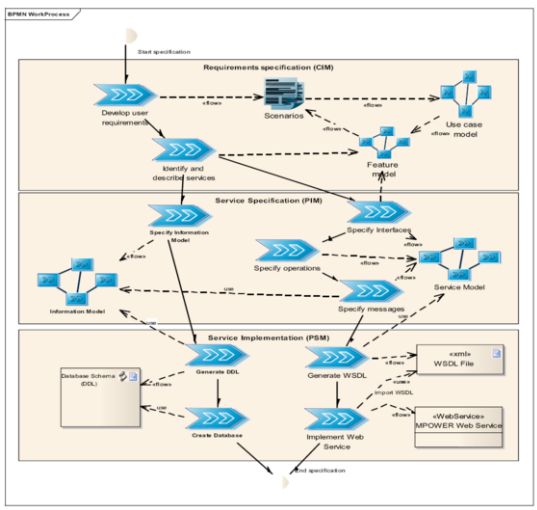

Figure 1- Development process and artifacts

Traceability model

In the development methodology, explicit and implicit trace links are established between the core development artefacts:

- Scenario ↔ Use case: implicit link by documenting the scenarios in each use case
- UseCase ↔ feature: explicit link using UML Dependency stereotyped with *<<trace>>*.
- Feature ↔ Service Model: explicit trace link between a set of features and a service. Implicit from feature to information model through the design of Service Messages (request/response)
- Service Provider ↔ WSDL file. Inserted feature traces as *<wsdl:documentation>* elements in the file.
- Documentation: direct export of navigable (HTML) models and text (RTF) from the design model.

The metamodel for explicit trace links uses the properties of a UML dependency, and includes trace link name/alias, source artefact name, target artefact name, free text field and, source and target roles.

Traceability Services

The trace information is stored within the design model and is used by the core traceability services [2, 11]:

1. *Trace navigation*: from any traced artefact (modelling element), navigate along (trace) dependencies back and forth.
2. *Coverage and orphan analysis*: query trace data for a list of traced elements and un-traced elements. Mostly used to find requirements that are not fulfilled (coverage) and elements that have no dependencies to other elements (orphans)
3. *Change impact analysis*: query trace data for information about which elements that will be directly or indirectly affected by a change in a specific element. Used to estimate cost of change requests.

A sound development methodology should support all these services.

Results

A total of 25 software services were designed using UML, realizing 168 features that were derived from 50 use cases, which involved 16 different actors and described 60 sub-activities from the 18 scenarios. 16 developers were involved in the design of the services during a 10-month period, following the methodology described in Figure 1. The complete actor and service model is reported in [6].

Trace links in the Patient Management Service

To demonstrate the traceability results, the Patient Management service is used as an example. Figure 2 shows the "Stakeholder management" use case and how it is related to actors and other use cases.

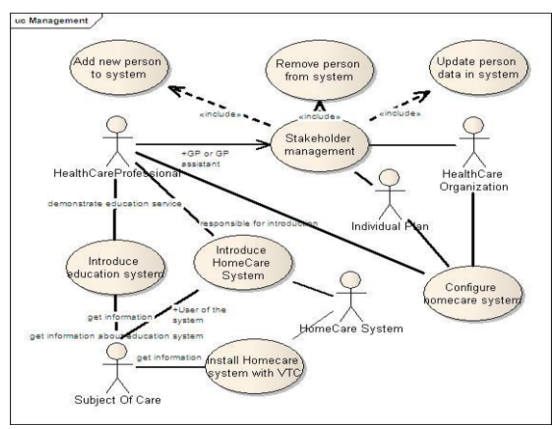

Figure 2- Use Cases for Management scenarios

The use case diagram shows an overview of the system "context", and more details can be found when looking at the properties for each use case element. The relationship from the *use case* to the *scenarios* is documented as a property of the use case element. A use case can be traced to more than one scenario description.

From the initial scenarios and use cases, a set of features are derived. A feature represents a high-level requirement for the system, and each *feature* is directly related to one or more *use cases* as shown for the Stakeholder Management use case in Figure 3. Using the use cases and features as input, the domain information model is designed and services identified following the process recommended by the OMG/HL7 Healthcare Service Specification Project in [7] and Erl in [8].

Each service design has a service rationale that traces from feature to service in a separate diagram. The features to be realized by the service provide useful information about the operations that are required on the services' interface, e.g., feature "*Get System user information for the person"* is implemented as the operations *getUserForPerson()* and *getUserForPatient()*.

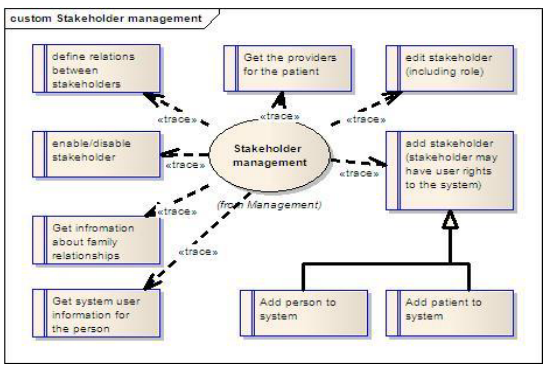

Figure 3- Features derived from the Stakeholder management use case

Traceability Services

From the models presented above, it is possible to provide the three core traceability services.

Trace Navigation

To navigate along (trace linked) elements one can use the modelling tool itself (e.g. Sparx Enterprise Architect), or an exported version of the model using any standard html browser (e.g. Opera, Firefox, Safari). Each model element is described with properties, appearance in diagrams and relationships to other model elements.

Traceability Matrix: Coverage and Orphan Analysis

To perform *coverage and orphan analysis*, most UML tools provide a relationship matrix query where the source, target, relationship type and direction can be used as query parameters. The result is a matrix showing which elements that have a relationship, indicated with a green arrow as shown in Figure 4. From the matrix it is possible to get an overview of which services that realizes which features. If a feature is not realized by any service, this indicates that not all features are *covered*, and a thorough inspection should be conducted. Similarly, if a service does not realize any of the features in the design model, it is an indication of an *orphan service*. A special situation can be identified if two services realize the same set of features.

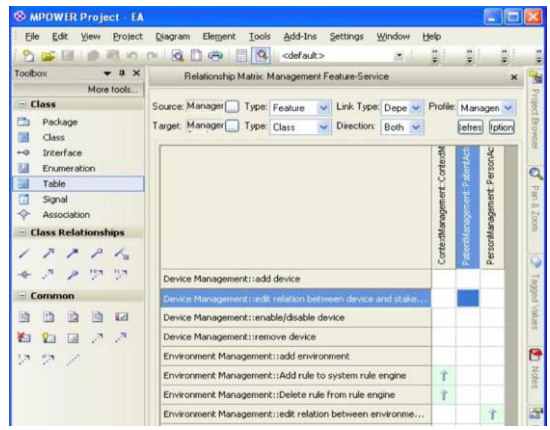

Figure 4- Coverage and orphan analysis matrix for management services and features

Change Impact Analysis

This analysis service can give product owners, administrators and project leaders a qualified estimate on the cost of making a change to the system design, based on trace links in the design model. A query to the design model can find all artefacts (services, features, actors, use cases, etc.) that have some dependency to the proposed system design change. Using the semantics in the model along with the experience from implementation, a qualified estimate on cost, risk factors and required man-hours can be made. Figure 5 shows a simple change impact visualization diagram. From the Patient Management service it is possible to visually trace the artefacts that are directly or indirectly dependent on its design. E.g., replacing the *Individual Plan* system with another system will require a reimplementation of five *features*, that each has a property value stating its difficulty.

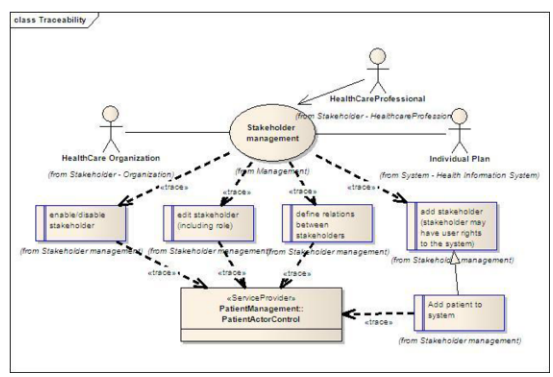

Figure 5- Example of model based view of traceability. All dependencies from between the actors, use cases, features and the final software service are shown in one diagram

Discussion

Using model-driven development and traceability solutions may improve documentation quality, and provide valuable information for many stakeholders in the design, development and maintenance phases of a system's lifecycle. However, a complete set of traceability services are not inherently incorporated in model-driven development and must be enforced by a design and development methodology. The proposed methodology offers these traceability services by using stereotyped UML dependency associations in implicit and explicit models.

Developer effort

For the developers, only minor effort is required to create the trace links. The view-based concept [13] used in MDD ensures that *model elements* are reused across *views (or diagrams)*, providing consistency and persistence of relationships. As a general principle, the more information that is incorporated in the trace data, the more advanced analysis services can be executed [2]. Nevertheless, for simple analysis services as is demonstrated herein, no additional trace information must be provided besides what is already in the model elements. Navigation in models using a html browser, reviewing relationships matrices for coverage / orphan analysis, and creating "query diagrams" for simple change impact analysis, are services that can be easily provided and used during design, development and maintenance using the proposed tools and methodology.

Benefits for healthcare information system development

To take full advantage of the trace information, the development methodology must incorporate both creation and inspection of trace information. An evaluation in the MPOWER project showed that traceability was especially useful for the developers [3].

For approval of software for medical devices, FDA strongly recommends traceability as a tool. The analysis services associated with traceability are considered powerful for improving the quality and documentation of the software. Furthermore, maintenance of legacy systems is a complex and costly process [15-17], also in the healthcare domain. Most hospitals have one or more systems that were implemented and put into production in the eighties. These systems are subject to maintenance to respond to new architectures, updates in standards, vocabularies and nomenclatures. There are many different standards and they are continuously being revised and new versions are ratified and made public many times during a system's lifetime.

Traceability services could be useful for managing maintenance processes.

Relationship to other approaches

Since 2004, the European Conference on Model Driven Architecture has organized a workshop on Traceability[2]. The conference papers reports on successful traceability projects. Also related to traceability is the increased use of business process modelling and simulation of care processes in modelling tools. IBM's Business Driven Development in Healthcare approach uses business process models and trace links to conduct advanced analysis and simulation [19].

Another model-based tool that utilizes traceability services are the three layer graph-based meta modelling tool (3LGM^2)tool from University of Leipzig, Germany [20]. The primary objective of this tool is "to describe, evaluate and plan health information systems." The 3LGM^2 tools could be used in the methodology described in the Figure 1, but in view of the fact that the 3LGM^2 metamodel is different from UML, the model elements cannot be reused in the succeeding system design and development phases.

Another model-driven healthcare software development process is the HL7 Development Framework [21]. The current version describes an approach were dependencies between artefacts are explicitly being modelled in UML. However, at the time of writing, the framework does not incorporate any traceability services.

Extending the traceability information

In terms of software management and maintenance, the meta information for trace link information play an important role, especially for the change impact analysis. Using UML as the core modelling language, one way to *extend expressiveness of trace links* is to use stereotypes and tagged values in a UML Profile. A stereotype can have tagged values such as implementation difficulty, importance level, creation date, creator and version dependencies. In addition, a profile can refine the graphical presentation of model elements and associations. Figure 6 shows an example diagram where green arrows indicate easy and red are critical/expensive implementation.

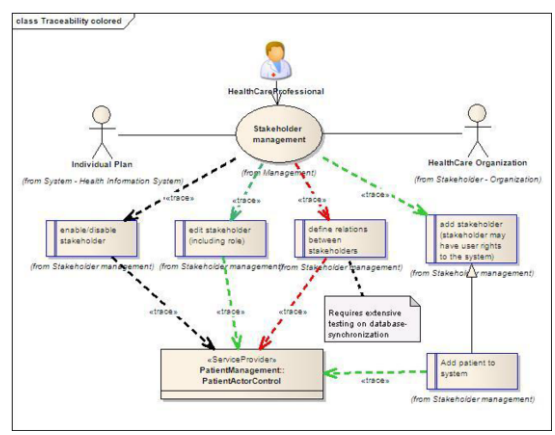

Figure 6- Example of a stereotyped change impact analysis diagram

In a larger system design, the colour coding of trace links (red for critical, black normal and green loose coupling), explicit notes and stakeholder icons (as shown in Figure 6) would make the visual analysis process more effective.

[2] http://www.ecmda-fa.org

Problems with implementation of traceability

There are some significant problems in implementing full traceability in software system development, as is discussed in [2, 22, 23]. The main problems are related to trace information sharing between tools and trace semantics. It is however possible to provide a partial traceability solution with existing tool interfaces and metamodels, and extensions could be provided from standardization organizations such as OMG, HL7 or even the FDA to further enrich the trace information database.

Concluding remarks

Traceability information can improve system development and maintenance processes. The core traceability services illustrated by Walderhaug et al [2] can be provided with a design methodology that utilizes the built-in UML dependency mechanism in a UML modeling tool. The results presented herein demonstrate that relevant and updated documentation can be made available to all stakeholders involved in a system's lifecycle.

Abstract

Health care organizations can gain great value from Information and Communication Technologies (ICT), yet, although there is growing awareness of the potential benefits associated with their use, results often fall far short of expectations. Each year, the "ICT in Health Care" Observatory – part of the Politecnico di Milano School of Management – outlines a profile of the role of ICT in the Italian health care industry, investigating current projects in terms of their impact on processes and organizations, implementation state of the art, governance models, and prospective pathways. The 2009 collaborative research process outlines the need for a change in the way health care CIOs approach technological and organizational evolutions. ICT departments lack vision, governance mechanisms, skilled resources, and top management commitment. This has led to a series of distortions in the innovation of Hospital Information Systems (HISs) and ICT departments themselves. Currently they are too concerned with day-to-day operations and delay comprehensive initiatives capable of leading to effective ICT-driven innovations. The paper points out the problems that health care organizations are tackling and how they are trying to solve them. The case of the Italian National Cancer Institute in Milan provides a valuable example of how a health care organization is developing its HIS.

Keywords:

ICT-driven innovation, Italian health care industry, Hospital information systems, ICT governance, Electronic patient record, Mobile & Wireless.

Introduction

Information and Communication Technologies (ICTs) have become necessary for Italian health care organizations – not only due to their increasing pervasiveness, but also to their ability to respond to the main innovation challenges currently facing the sector: the rationalization of health care costs [10], and the increase in the quality of health care processes [3].

The enormous volume and the intricate complexity of clinical and administrative information to be managed, make ICT essential for both running and innovating health care organizations. To understand this, it is sufficient to think of all the potential benefits that Hospital Information Systems (HISs) could achieve with a digitally-integrated management of clinical information flows, done with Electronic Patient Records (EPRs). Unfortunately, this kind of strategic role has yet to be achieved. Actually, most health care organizations:

- Continue to barely give them a second thought as a source of innovation [5], and
- Don't adequately analyze the organizational changes required to make all the benefits associated with ICT projects become a reality [1].

Thus, instead of being considered strategic resources, ICTs are often simply confused with other health technologies, and generalized as one of the drivers in the rising cost of the health care sector. Helping companies analyze and improve their information streams, EPRs, HISs and – more generally – ICTs, can be seen as a fundamental set of resources able to generate corporate benefits – with the coordination of other medical technologies and health care practitioners. In order to do this, health care organizations need more models, tools and skills on which to base the management of ICT.

Materials and Methods

This study is based on a broader and continuative research initiative promoted since 2007 by the Politecnico di Milano School of Management, i.e. the "ICT in Health Care" Observatory (IHCO), which focuses specifically on the analysis of ICT-driven innovation in the Italian health care industry[1].

Every year, the Observatory follows a stream of collaborative research [11] led by IHCO researchers, and is enriched with the involvement of practitioners in the gathering and analysis of the data pertaining to the research problem. The research stream, outlined in Figure 1, is a combination of a quantitative panel of electronic surveys, several qualitative in-depth case studies, and a series of focus groups called *Advisory Boards* (AB).

[1] The IHCO is one of the 30 Observatories specifically focused on the study of ICT and Management that the Politecnico di Milano School of Management started in 1998.

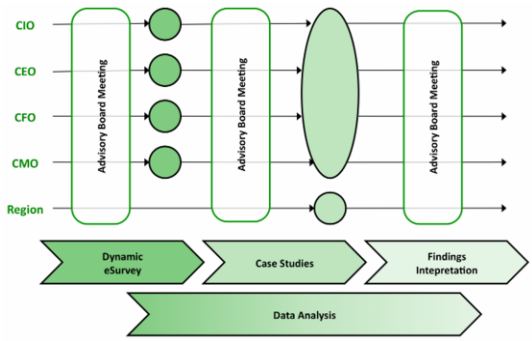

Figure 1 - The collaborative research process used by the IHCO

Every year, an electronic survey is created and delivered to a sample of more than 500 Italian health care CIOs – from representative organizations of varying types and sizes in different geographical areas. In 2009 [8], a 24% response rate was achieved thanks to: (i) a specific survey design[2], (ii) a series of comprehensibility and completeness tests from pilot respondents, and (iii) a set of improvements established with the AB. Every year, a second set of surveys is delivered to the Strategic Board – Chief Executive Officer (CEO), Chief Financial Officer (CFO) and Chief Medical Officer (CMO) – of the same health care organizations of responding CIOs, in order to cross-validate responses given.

A comparative analysis of more than 50 in-depth retrospective case studies is performed every year. The selection of target organizations is based on: (i) dimension of ICT department[3], (ii) ICT strategic importance[4], (iii) ICT projects, and (iv) AB suggestions. Data is gathered through a series of semi-structured interviews given to the CIO, CEO, CFO and CMO. The interviews are based on a common protocol constructed according to survey responses and an *a priori* analysis of the health care organization. Other information came from organizational charts, HIS architectural schemes and other materials shared with the research group (data triangulation).

The AB is a multidisciplinary focus group that advises and helps in directing the focus of the research, in interpreting data, in anticipating future research issues and confirming results. The group counts more than 50 representatives among which: (i) CIOs of the principal Italian health care organizations, (ii) National and International health technology suppliers, (iii) experienced professionals from Italian national health care associations, and (iv) other research partners. The annual AB contribution to research counts three key meetings (see Figure 1). The first one deals with informal discussion about annual research objectives and priorities in the data gathering process. In the second meeting, preliminary results are discussed, and the AB suggests potential best practices on which to perform annual case studies. In the last meeting, overall results and explanations are discussed in order to test, review and confirm them.

[2] The survey is designed with semi-closed questions (to balance usability and speed) with the possibility of expounding on each question.
[3] Measured with the rate of ICT FTE to overall organization employees.
[4] Measured in budget terms.

Results

The Strategic Value of ICT and HIS Governance

A constant piece of evidence emerging every year is the extreme heterogeneity in the ways in which Italian health care organizations give ICT a strategic value [8]. Interviews pointed out that ICT maturity is strongly related to: (i) the strong regional connotation of the Italian health care industry (including providers and vendors as well) and (ii) the historical socio-technical context in which health care organizations operate.

Thus, in order to clearly understand the real level of diffusion of ICT tools among Italian health care providers, surveys analyzed the main areas whose processes are supported by ICT. These areas are classified in: (i) primary activities of health care delivery, (ii) support activities, and (iii) network processes. The matrix in Figure 2 shows past (from 2007 to 2009) and expected (from 2010 to 2012) investment levels in these areas.

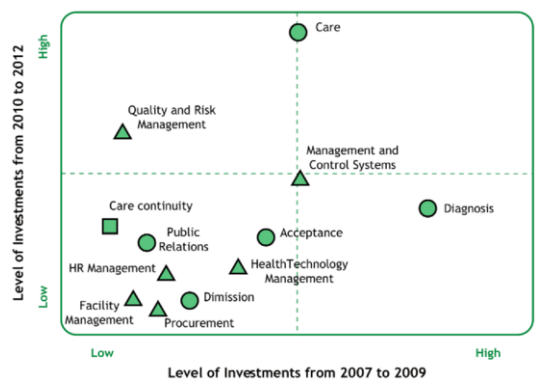

Figure 2 - Past and future ICT investment priorities areas of Italian health care CIOs (Circles = Primary activities areas; Triangles = Support activities areas; Squares = Network processes areas)

The majority of primary processes were evaluated as currently positively/highly supported (e.g. the diagnostic area), apart from core care activities (e.g. bedside, EPR, and so on). ICTs also play a relevant role in clinical support activities, but with the exception of core areas like quality assurance and risk management.

Interviews emphasized that almost all health care organizations implemented ICT solutions with the main aim of increasing resource efficiency. For example it's interesting to consider the contribution that ICT has given in the last few years to time-consuming activities like Admissions, or to costly "material-consuming" activities like those performed in radiology [4]. On the other hand, difficulty in introducing ICT in core care processes can be only partially explained by a low maturity level of market solutions: the implementation of these pervasive tools requires the agreement of all the actors participating in health care service delivery, and a high level

ing in health care service delivery, and a high level of structural integration within health department processes. ICT can play this "linking" role, as confirmed by 80% of organizations, but the level of integration of HIS remains low. Drawing on evidence from the case studies performed, approximately three out of four Italian health care organizations either aren't structurally integrated, or don't realize a level of integration able to lead to future ICT-driven innovation.

Low financial support – often pointed out as the main problem – is mainly a reflection of the low strategic commitment on the part of the strategic board, which doesn't have a clear idea about how ICT can have an impact that goes beyond mere efficiency. Reasons are multiple and range from a lack of a technological perspective on the part of CEOs, CFOs and CMOs, and the inability of CIOs to clearly propose all the advantages tied to ICT solutions, to the need for high investments to reach concrete organizational results[5].

Without a critical mass, ICT employees are forced to play help-desk or hardware manager roles. Very few learning processes are initiated to enhance their technical skills. Leadership programs are practically inexistent. Turnover rate is very low, and many difficulties are found in attracting professionals from other sectors. CIOs tend to ascribe all these criticalities to exogenous causes, rather than internal inadequacy, and to blame operational workload instead of their own incapability to face it. We found [8] that the CIO himself often has a narrow strategic view hindering an approach to innovation. This is due to: (i) a low level of managerial capabilities, (ii) difficult alignment with corporate strategies and (iii) overuse of technical language in strategic board interactions, not abstracting from ordinary operations. Hence, most of the problems can be referred to governance – not to technological matters.

The Role of Electronic Patient Records

According to Figure 2, clinical care is one of the main areas that received, receives and will receive most of ICT investments in health care. This area is highly representative of the necessity of integrated ICT-based solutions, in order to achieve affordable and effective ICT-driven innovations in health care [7]. Clinical care increasingly requires clinicians to access patient record information that: (i) may be distributed across multiple systems, and (ii) is represented as a mix of narrative, structured, coded and multimedia entries. EPR is the ICT-based solution that many health care CIOs are adopting and evolving to tackle these strategic clinical issues, and that have the highest potential to provide advanced integration capabilities to the other HIS components[6]. The importance of EPR in the evolution of HIS's integration led IHCO to include a vertical analysis on this topic in the research process [8].

A comparison between budgets allocated to EPR shows a significant increase in the number of EPR investments than will exceed 500,000 €[7]. These efforts potentially could justify the adoption of effective integrated solutions. However, surveys and case studies outlined a still fragmented situation. Literature analysis [9] allows the identification of five functional areas that characterize EPR:

- *ADT Area*: often integrated with the ADT system, this area manages patient admissions, discharges and transfers within the hospital, as well as vital statistics and administrative documentation (e.g. informed consent).
- *Diagnostic Area*: the features in this area allow exam requests and report delivery from/to wards.
- *Clinical Dossier*: this area embraces the management of all medical and nursing sheets, including initial assessment, vital signs automated monitoring, anesthesiology documents, OR reports, etc.
- *Therapy management*: this area includes support to prescription and administration of drugs, transfusions, nutrition, etc.
- *Out-patient management*: this area manages admission and medical reporting in case of out-patients, and feeds the patient's EPR with information like preliminary report or follow-up examinations.

Figure 3 shows the current and the expected percentage of diffusion of these functional areas in the research sample. Clinical Dossier (e.g. nursing sheets, vital signs monitoring) and Therapy Management are the functional areas with lower diffusion and on which CIOs recognize that they have to work in the future. Unfortunately these areas not only have a key impact on clinical activities, but also are the ones that need higher levels of integration in order to allow EPR to really become a useful clinical tool[8]. Case studies confirmed that the lack of integration with the rest of HIS and the absence of an enterprise-wide approach to solutions are the main limit of current EPR projects.

Case studies and AB meetings showed that the main hinders are, again, not related to technology, but to the extremely complex socio-technical nature of clinical processes (even more if we consider Public providers). Apart from the lack of support often occurring after implementation, the real criticalities are (i) the singling out of actual medical necessities and (ii) processes mapping – mainly because head physicians tend to act almost autonomously, without the real involvement of ICT department. External ICT supplier involvement is almost always operational or consultancy-oriented and in the few cases in which the relation is continuative, CIOs don't delegate much, and work alongside them – even in highly outsourced operations.

[5] The research reveals a generalized distance between the CIO and the top management: only 57% of surveyed CIOs are accountable to the CEO, while many ICT Units belong to Administrative or Technical Departments. Few CIOs act as true C-Levels, and often the ICT Department is not seen as a relevant actor in strategic planning activities – especially in comparison with CMO and CFO.

[6] E.g. Clinical data repository, ADT System, Diagnostic Area Systems, Order Management Application, middleware, etc.

[7] If from 2007 to 2009 the % of investments higher than 500,000 € was 6%. This percentage will increase to 24% by the end of 2012.

[8] Case studies pointed out that the investments in Clinical Dossier and Therapy Management areas will be driven by mobile hardware acquisitions. Surveys revealed that nowadays there is a clean prevalence of desktop PCs (89% of cases), while the use of fully mobile devices is still not widespread. This is a strong barrier against the implementation of really paperless health care organizations, because key clinical features must be delivered bedside with a proper device in order to support daily routine (e.g. PDAs for nurses administering drugs or transfusions, MCAs to support doctors filling daily records).

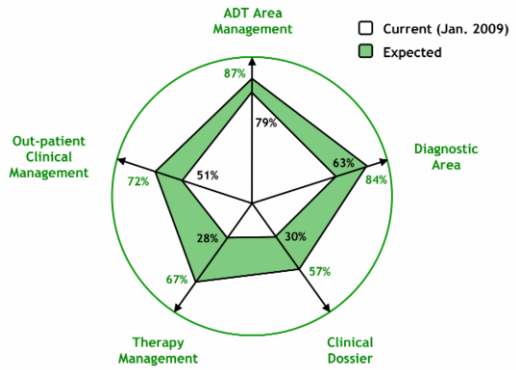

Figure 3: The January 2009 and expected diffusions of EPR functional areas

The AB meeting proposed a few guidelines to change this situation, which were also applied in the best case studies. First, to effectively sustain the change required in health care, CIOs need to work on their capabilities, as already done in other sectors [6]. In 65% of surveyed health care organizations, CIOs play a merely operative role. Obviously, this isn't sufficient: possessing more CIO capabilities doesn't necessarily constitute an ICT strategic role. The ICT department won't generate ICT-driven innovation until it has knowledge of clinical processes, relational capabilities and the ability to exploit external knowledge, working alongside Medical Offices. Thus, ICT governance models have to direct their attention to core health care businesses; to designate the ICT department as the main interface between the supply and the demand of the health care organization, and to develop strong absorptive capabilities to catch external innovation enablers[9].

A Case Study

Founded in 1925, the National Cancer Institute (NCI) in Milan (in Italian *Fondazione IRCCS Istituto Nazionale dei Tumori*) is a top-tier Scientific Research and Treatment Institution which has achieved renowned excellence in the field of preclinical and clinical oncology research and care. About 2,200 patients pass through the institute every day – with an annual average of 900,000 out-patient treatments, and more than 15,000 surgical treatments (including many liver transplants).

The NCI has consolidated expertise in: (i) exploiting ICTs to rapidly switch from experimentation to clinical practice, and (ii) developing ICT solutions able to increase processes quality in day-to-day critical areas. The interviews with the CIO and the Strategic Board outlined that the reasons behind these results are both internal and external to the ICT department[10]. The CIO has externally recognized leadership and acts as a true C-Level director. Her style of management continually strives toward the achievement of coherence within ICT and organizational strategies; and Strategic Board recognizes her key role in the definition of NCI strategies. This greater interaction with internal and external organizational actors could potentially create a loss of focus, trying to adapt to very different business needs: robust methodologies were implemented to prioritize tasks and let all ICT-driven synergies emerge.

All these targets could be met thanks to (i) a comprehensive socio-technical perspective associated with ICT-based solutions, and (ii) a homogeneous development all along the different evolutional paths of ICT-driven innovations. Taking a closer look at the five functional areas of EPR described above (see also Figure 3), we find the following:

- *ADT Area*: this is the first area that was digitalized – mainly for historical reasons. Recently NCI replaced the old central mainframe with modern systems, compliant to up-to-date requirements and international interoperability standards to feed EPR.
- *Diagnostic Area*: all core diagnostic departments are supported by state-of-the-art solutions. Only smaller labs (e.g. genetics) are supported by local applications, not integrated within the HIS.
- *Clinical Dossier*: NCI is supporting Lombardy in the test of a new clinical repository of (i) digitally signed medical reports, (ii) structured data, (iii) events (e.g. transfusions, surgery) and (iv) many others, from clinical placement to exam requests. Physicians will be able to browse through a patient's clinical history and retrieve more and more clinical information. Moreover, this clinical repository will feed patients' Regional Health Records (Italian FSE) as well as Pathology Networks.
- *Therapy management*: NCI is also leading a research program on clinical risk management in chemotherapy (funded by the Italian Ministry of Health). The program aims to develop clinical and organizational guidelines, as well as tools based on mobile & wireless technologies, in order to better integrate the therapy management system with the rest of HIS.
- *Out-patient management*: the NCI outpatient solution is fed by the Central Booking System and supports physicians for the digital signing of visit reports.

The use of mobile devices is also spreading within wards. NCI of Milan can be considered a forerunner amongst European health care organizations in its application of RFId technologies [12][11]. All the benefits associated to these last ones [2] are

[9] It is interesting to remark that the Lombardy region has recently established a set of mandatory guidelines for the development and the implementation of EHRs. Guidelines emphasize the relevance of integrated hospital-wide solutions, as well as the importance of specific functional areas like Clinical Dossier and Therapy Management. In Italy these kinds of Regional initiatives have a strong impact on the priorities that health care organizations set in order to develop their HISs. Surveys and case studies showed these changes from Region to Region.

[10] To evaluate them as homogeneously as possible, the external reasons were identified with the help of CIOs and then compared with the opinions of the CEO, CFO and CMP; the determination of internal reasons followed the inverse emergence and ratification process.

[11] Current key projects address: (i) general patient and staff identification, (ii) safety and traceability of transfusions, (iii) tissue bank

also associated with a major operational flexibility which is core, not only to clinical daily support but also to long time ICT-driven innovation.

Conclusion

The 2009 annual research done by IHCO outlines a complex scenario for ICT-driven innovations in the Italian health care industry:

- In order to be effective, research on EPR, HIS and ICT-driven innovation in health care will have to progressively involve practitioners in cyclical research processes of collecting, providing feed back, and reflecting on data;
- Geographical and historical contexts strongly affect ICT use in health care organizations;
- The major hinders to an organic and effective HIS development are related to governance, not to technology;
- The lack of effectiveness of EPR, HIS and – more generally – of ICT-driven solutions is mainly related to: (i) an organizational culture that still does not perceive ICT as a process support lever and (ii) an ICT department without the competences and poise required to play a real strategic role;
- To solve these problems health care organizations must work on the profile of CIOs and on the ICT department organization and governance mechanisms, with the objectives of bridging the gap between technological opportunities and clinicians' needs;
- In order to be effective and affordable, the development of EPR and/or HIS has to follow a clear evolution strategy managed by the ICT department in close coordination with the strategic board, medical departments and health care technology suppliers;
- The ICT-driven innovation in clinical core processes requires high levels of integration among specific ICT solutions. HISs and EPRs suggest that a lack of interoperability standards could become a barrier to integration and, thus, to ICT-driven innovation.

The analysis of the case of the Italian National Cancer Institute in Milan seems to confirm these points.

Acknowledgments

The authors would like to thank all the Italian health care organizations, health technology suppliers, national health associations and other IHCO partners for their participation in the research process. The authors also would like to acknowledge the Italian Ministry of Health for funding the project "Towards a complete competence framework and an integrated solution for patient safety in chemotherapy".

operations, (iv) chemotherapy dilution and administration (v), quality assurance in bedside radiology activities, (v) radiotherapy machines.

Abstract

Background: Surveillance of healthcare-associated infections is essential to prevention. A new collaborative project, namely ALADIN, was launched in January 2009 and aims to develop an automated detection tool based on natural language processing of medical documents. Objective: The objective of this study was to evaluate the annotation of natural language medical reports of healthcare-associated infections. Methods: A software MS Access application (NosIndex) has been developed to interface ECMT XML answer and manual annotation work. ECMT performances were evaluated by an infection control practitioner (ICP). Precision was evaluated for the 2 modules and recall only for the default module. Exclusion rate was defined as ratio between medical terms not found by ECMT and total number of terms evaluated. Results: The medical discharge summaries were randomly selected in 4 medical wards. From the 247 medical terms evaluated, ECMT proposed 428 and 3,721 codes, respectively for the default and expansion modules. The precision was higher with the default module (P_1=0.62) than with the expansion (P_2=0.47). Conclusion: Performances of ECMT as support tool for the medical annotation were satisfactory.

Introduction

Surveillance of Healthcare-Associated Infections (HAI) is an important activity and a real burden in the context of control and prevention. The impact on patients' health and related healthcare cost are highly significant and a major concern even for the richest countries. Furthermore, some issues were addressed concerning the workload and costs generated by this surveillance.

Alternative methods based on automation of detection procedures were experimented in different facilities. In this context, the electronic health records (EHR) represent a unique opportunity for infection control practitioners (ICP) to automate manual processes. Few experiences of applying data and text mining techniques for monitoring adverse events are reported in literature [1-2]. Data mining offers methods that can recognize patterns in these large data sets and make them actionable: e.g. the Data Mining Surveillance System uses data from the clinical laboratory and hospital information systems to create association rules linking patients, sample types, locations, organisms, and antibiotic susceptibilities [1]. The Geneva team was testing a classifier to distinguish between HAI and non-HAI [3].

The objective of the overall ALADIN Project [5] is to develop an automated HAI detection tool based on screening French natural language documents and reports of the EHR, especially from discharge summaries. This project began in January 2009 and will last 3 years. For the evaluation of the tool, the gold standard used will be manual annotations of these medical documents by using a French medical multi-terminology indexing tool (French acronym: ECMT). The annotation will firstly provide the correspondence between terms used in current medical language and not directly available in the standardized terminologies and secondly it will provide standardised data for building algorithms of detection. The objective of this study was to evaluate the French ECMT tool, in terms of recall and precision for the annotation of natural language medical reports of healthcare-associated infections.

Material and Methods

Development of the HAI detection tool

The first step of the HAI detection tool was the development of a clinical questionnaire by the CNRS-UMR 5558 team (on a MS Access computer application named NosIndex). The purpose of this questionnaire is to enable ICPs from 4 French University hospitals (Lille, Lyon, Nice, Rouen) to manually collect all relevant medical terms (symptoms or diagnosis, medical intervention, medication, microorganisms, medical

imaging…) from 2,000 medical reports. The ICPs will also enter their conclusions regarding the outcome: suspicion of HAI or not. The manual annotation of each medical report will be conducted independently by two different ICPs. In case of annotation discordance, the two ICPs will meet for a consensus procedure. The final decision regarding the outcome "suspicion of HAI or not" will serve as gold standard for the evaluation of the detection tool performances. From the 2,000 medical reports selected for this study, 400 HAI reports and 400 reports without HAI will be randomly selected for the evaluation of the detection tool. The gold standard used for this evaluation in terms of sensitivity and specificity will be the manual medical annotation.

Building a French Health Multi-Terminology automatic indexer (ECMT)

All relevant medical terms selected by the ICPs and entered in the questionnaire will be coded by using the tools developed by the CISMeF team, which include several health terminologies.

In 2005, the CISMeF team decided a strategic shift: from a mono-terminology approach based on the MeSH thesaurus to a multi-terminology approach based on the main health terminologies available in French. Some of them are integrated in the UMLS metathesaurus; some are not because they are French terminologies (e.g. CCAM, DRC, Orphanet). These terminologies have their respective objectives and may explain why the health sector is so rich in terminologies: the MeSH is devoted to documentation, SNOMED to describe patient records, ICD10 to epidemiology, CCAM to procedures, ATC to drugs, ICPC2 and DRC to general (or family) medicine, ICF to disability. To adapt the CISMeF information system to the new paradigm "Multi-Terminology approach", the CISMeF team had restructured the CISMeF database models to integrate as generically as possible the various health terminologies. These terminologies are also integrated into a Health Multi-Terminology Server (HTMS) [6], which is based on the ITM platform of the Mondeca private company (URL: http://www.mondeca.com/**)**.

The new ECMT tool presented here is largely inspired by the CISMeF algorithm for information retrieval for the Doc'CISMeF search engine [9] and F-MTI [7], which is a multi-terminology automatic indexer, developed in collaboration with the Vidal Company. As most of indexing tools, it is language-dependant and works for the French language.

The EMCT tool has two query modules: one default module based on bag of words algorithm [7] and one expanded module based on textual indexing, using Oracle text indexing®. The information retrieval allows retrieving all the terminologies descriptors that contain the words of the query, with a minimal score, which depends on the number of query words. By construction, the expanded module will provide more results than the default module.

The ECMT tool has four main steps for the default module:

- Step 1: Query normalization

The unimportant words are removed from the initial query, and then the phonetic spelling and the stems of the remained significant terms are extracted and alphabetically sorted out.

- Step 2: Identification of the descriptors

For each terminology, 0 to (n-1) words from the set of the significant terms are removed in order to identify the descriptors.

Query Example: lead intoxication in France (intoxication du plomb en France)
step1: {intoxication, intoxi, 1toksikasion, France, franc, fr4s, plomb, plomb, plan}
step2: example for the thesaurus MeSH
-remove 0 word: identify the descriptor composed of {intoxication, france, plomb}
-remove 1 word: identify descriptors composed of {intoxication, france}, {intoxication, plomb}, {france, plomb}.
=> Identification of the descriptor "intoxication plomb"
-remove 2 words: identify descriptors composed of {france}

- Step 3: Determination of affiliated descriptors (MeSH qualifiers) for each identified descriptor.
- Step 4: Supplement the query indexation by the MeSH indexation rules and pharmacological action rules (MeSH is the main thesaurus for indexing in CISMeF). For example, if the query is indexed by the supplementary concept "racecadotril", it will be indexed also by the descriptor "antidiarrheals" describing the pharmacological action.

The ECMT tool can be queried by a human but much more interestingly by any software application using a dynamic URL as long as this software application is connected to the Internet. In both cases, the tool is provides an XML answer which can be displayed for the human or integrated in the software application, eventually after a filtering process among the 9 available terminologies.

The ECMT algorithm is now available freely for the research community. It will become a commercial product thanks to the collaboration with the Vidal Company in the coming months. The URL for human (POST method) is: http://doccismef.chu-rouen.fr/Interpreteur.html. The URL for computer (GET method) is: http://doccismef.chu-rouen.fr/servlets/Interpreteur?Mot=enfant+asthmatique[2].

Development of a software application (NosIndex) for the manual annotation of medical reports

In the context of this project, a MS Access application (NosIndex) was developed by the CNRS-UMR 5558 team in order to collect the manual annotation of the medical reports. Figure 1 summarizes the process and exchanges between NosIndex and ECMT. When an ICP enters an original term

[1] The query in French means: asthmatic child

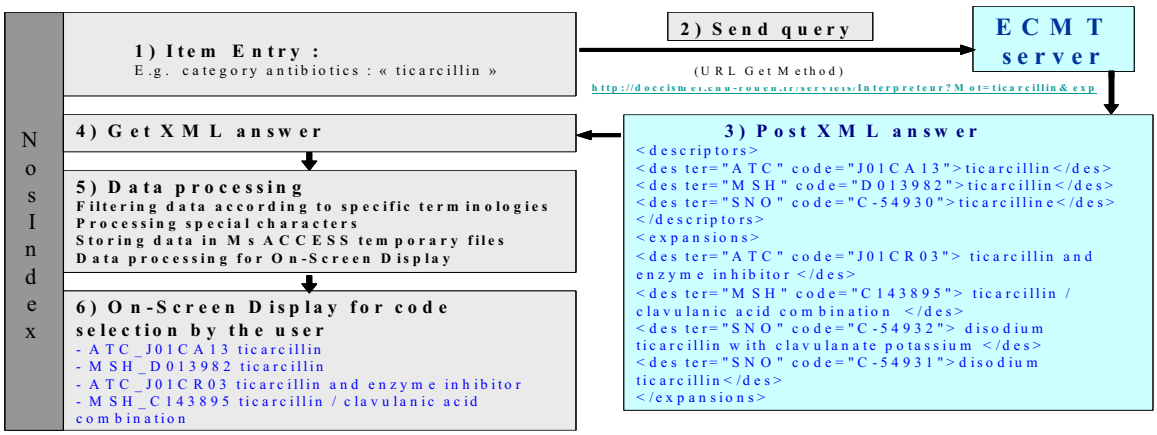

Figure 1 - Process and exchanges between NosIndex and ECMT

from the medical report into NosIndex by using a standardized clinical questionnaire, the application exports the request to the ECMT tool and imports the XML file containing all the corresponding codes. The process lasts 2 to 3 seconds before the ICP can visualize all the proposed codes. Then, the ICP can select the most appropriate one. If it does not find any satisfying code, the term will not be coded by the ICP and the term will be in a second step analyzed by semantic experts for decision. The structured questionnaire was developed on the application in order to classify all the medical terms relevant for implementing the detection algorithms of HAI.

The following categories (symptoms/diagnoses, bacteriological exams, type of microorganism, biological exams, radiological exams, antibiotics, and type of surgical intervention) were selected by HAI experts and have been coded specifically in order to limit the noise generated by the use of the 9 terminologies. (a) Symptoms/diagnosis: ICD10, SNOMED 3.5, MeSH; (b) Bacteriological exams: SNOMED3.5, MeSH; (c) Type of microorganisms: SNOMED 3.5; (d) Biological exams: SNOMED3.5, MeSH; (e) Radiological exams: SNOMED 3.5, MeSH, CCAM; (f) Antibiotics: ATC, MeSH; (g) Type of surgical intervention: CCAM, MeSH. The NosIndex application filters the results provided by ECMT, depending on the category of the medical terms. These filters were chosen manually by the expertise of the ALADIN project members.

Evaluation methods of the ECMT tool

Data sources

Medical discharge summaries from patients with hospital acquired infection managed in intensive care units (n=42), orthopaedic surgery (n=12) and digestive surgery (n=8) of the Lyon University Hospital were randomly selected. An ICP evaluated the terms proposed by the ECMT when a medical term was entered in NosIndex. From these medical reports, the first 50 terms (not redundant) for symptoms/diagnosis and the first 30 terms for other categories were manually selected by an ICP. He entered the terms in NosIndex and evaluated each term proposed by the ECMT. The level of satisfaction of the term proposed was evaluated by using the following score: (a) 0 if no match; (b) 0.5 if approximate match (too precise or on the contrary too little accuracy); (c) 1 if perfect match.

Evaluation of the ECMT default module

We defined Recall R_1 as the number of relevant terms found by the ECMT default module divided by the total number of relevant terms provided by the two ECMT modules.

We defined precision P_1 as the number of relevant terms found by the ECMT default module divided by the total number of terms provided by the ECMT default module. F_1-measure was calculated as follows:

$$F_1 = \frac{2P_1R_1}{P_1 + R_1} \quad (1)$$

An average precision and average recall were calculated by category of medical terms. It is then possible to calculate an average precision by category, as the average of precision values for each term of this category (e.g. the average precision = $(P_1 + P_2 + P_i \ldots + P_n)/n$, with P_i = precision for the term i and n = total number of terms evaluated for this category). It is also possible to calculate an average recall by category.
Then, an overall mean average precision and mean average recall were calculated, as followed:

- Mean average precision = average of the average precision for each category;
- Mean average recall = average of the average recall for each category.

The exclusion rate is defined as the ratio between the number of terms not found by the ECMT default module and the total number of terms evaluated. This exclusion rate was calculated by category and overall.

Evaluation of the expansion performances

We defined the precision P_2 as the number of relevant terms found by the ECMT expansion module divided by the total number of terms provided by the ECMT default module. Recall

and F-measures were not calculated because no gold standard is available for determining the denominator. For example, the number of relevant terms existing in the multi-terminology indexing tool. An average precision was calculated by category. The same terminologies as for the ECMT default module were selected by category. The exclusion rate is defined as the ratio between the number of terms not found by the ECMT expansion module and the total number of terms evaluated. This exclusion rate was calculated by category and overall.

Results

The results of the ECMT tool are summarized in Table 1. For the evaluation of the 237 medical terms of medical reports related to HAI, the number of terms proposed by the ECMT default module was 9 times less than the number proposed by the ECMT expanded module (428 vs. 3,721). Then, the overall precision P_1 (ECMT default module) was higher than the overall precision P_2 (ECMT expanded module) (0.62 vs. 0.47).

The overall F-measure was 0.59 with a minimum of 0.46 for the category "bacteriological exams" and a maximum of 0.71 for the category "antibiotics". The overall recall R1 was 0.58 but important variations were observed between categories (min: 0.45; max: 0.70). The only use of the default module could be satisfactory (R_1= 0.70) but for other categories and particularly for the type of surgical intervention (R_1 = 0.45), the expansion module improved consistently the number of relevant terms proposed for annotation.

The overall exclusion rate for the default module was 0.15. The expansion lowered significantly the exclusion rate of 0.15 to 0.11. By category, the expansion lowered significantly the exclusion rate for "radiological exams" (from 0.13 to 0.06) and for "type of surgical intervention" (from 0.22 to 0.09). Exclusion rate was rather small for four categories with both modules. The exclusion rate remained important for two categories: 0.26 for bacteriological exams and 0.23 for antibiotics.

Table 1- Summarized results of the ECMT evaluation

	Number of terms evaluated	**Number of terms (ECMT default module)**	**Number of terms (ECMT expansion)**	**Evaluation "default module"**			**Evaluation "expansion"**	**Exclusion rate**	
	N	N	N	P1[3]	R1[4]	F-measure	P2[5]	Default module[6]	ECMT expansion[7]
Symptoms/ diagnosis	50	141	1424	0.60	0.62	0.61	0.42	0,06	0.04
bacteriological exams	31	63	122	0.41	0.51	0.46	0.38	0,32	0.26
type of microorganisms	31	38	147	0.77	0.63	0.69	0.64	0,10	0.06
biological exams	30	43	639	0.77	0.60	0.67	0.43	0,07	0.03
radiological exams	32	55	989	0.53	0.53	0.53	0.38	0,13	0.06
Antibiotics	31	23	38	0.74	0.7	0.72	0.71	0,23	0.23
Type of surgical intervention	32	65	362	0.54	0.45	0.50	0.40	0,22	0.09
Overall	237	428	3721	0.62	0.58	0.59	0.47	0,15	0.11

[3] e divided by the total number of terms provided by the ECMT default module
[4] R1 = number of relevant terms found by the ECMT default module divided by the total number of relevant terms provided by the two ECMT modules
[5] P2 = number of relevant terms found by the ECMT expansion divided by the number of terms provided by the ECMT expansion
[6] Exclusion rate (default module) = = ratio between the number of terms not found by the ECMT default module and the total number of terms evaluated.
[7] Exclusion rate (expansion) = ratio between the number of terms not found by the ECMT expansion module and the total number of terms evaluated.

Discussion

The main objective of this study was to evaluate the ECMT tool, in terms of F-measure, recall, precision and exclusion for the annotation of natural language medical reports of healthcare-associated infections in French. If the overall F-measure could be considered as satisfying (0.59), some efforts need to be made to improve the F-measure for certain categories (bacteriological exams, radiological exams and type of surgical interventions).

An important result of this study is the relative good overall precision P_2 (ECMT expanded module) compared to the overall precision P_1 (ECMT default module) (0.47 vs. 0.62), although the ECMT expanded module provides 9 times more terms than the ECMT default module (3721 vs. 428). Furthermore, the overall exclusion rate of the ECMT expanded module is rather small (0.11).

We need to improve the results for two categories: bacteriological exams and antibiotics. For the category "bacteriological exams", we plan to add a partial translation of LOINC.

For antibiotics, we have already translated in French 8,200 out more than 180,000 MeSH Supplementary Concepts [8]. We plan to go further. We have also planned to increase our cooperation with the Vidal company, leader of French drug database market.

This evaluation of the ECMT tool was done in a specific context, namely healthcare-associated infections, with the purpose to help the professionals who are not experts in standardized terminologies annotate medical reports. A software application can be easily developed as an interface for annotation of various medical topics (e.g. epidemiological studies, clinical research, adverse event surveillance…). By filtering relevant terminologies and by selecting default or expansion module depending on the medical category of terms, the investigators can find a satisfactory balance between inevitable noise and lack of precision.

Conclusion

The aim of this study was to evaluate the performance of the ECMT as a support tool for the manual medical annotation. This study showed that the performance of the tool was good enough for helping ICPs to annotate medical reports with the different standardized terminologies. In parallel and in the context of the ALADIN project, the ECMT tool will also be used for the development of an automated HAI detection tool.

A Lab-EMR Interoperability Profile as an eHealth Architecture Component for Resource-Constrained Settings

Abstract

Implementation of computerized systems in resource-constrained settings have been gaining traction as a means of improving the delivery of health care, the use and reuse of information, and providing a standards-based capacity for assessing the process and impact of health care. In a resource-constrained environment, systems are often implemented as stand-alone entities focused on specific care activities (for example, delivering antiretroviral therapy). As such, in many countries, taking a generalized approach to linking electronic medical record systems with laboratory information systems (EMR-LIS) is an important area in which to achieve interoperability. In this paper we describe a scenario of use and information interaction interoperability profile based on our experience implementing EMR-LIS integration in two resource-constrained settings. Of significance, the profile emphasizes queued matching in order to avoid mutual dependence while achieving interoperability between systems.

Keywords:

Clinical laboratory information systems, Developing countries, Computerized medical record systems, Public health informatics, Systems integration

Introduction

In resource-constrained settings, both government and donor agencies are emphasizing implementation of computerized systems to improve the use and reuse of information, to improve the delivery of health care, and to assess the process and impact of that care. While operational efficiency, as well as internal and external goals in the distribution and reuse of data are motivations for using such systems, their implementation is a challenge. Identified barriers to implementation have included funding limitations, variety in health care data, the differing ways used to represent those data, and the variety of locations in which it is collected and stored.[1] In a resource-limited environment, how does one support the exchange of data required for effective use and reuse?

This paper proposes the use of interoperability profiles as one component of an eHealth architecture framework that integrates laboratory information systems (LIS) and electronic medical records (EMR) in resource-constrained environments. The goal of this interoperability profile is to enable point-to-point healthcare information exchanges between these two primary and heterogeneous health information systems.

Following background information regarding health architectures and the accepted protocols for creating and elaborating the components and steps of an information interaction profile, we describe a scenario of use and interoperability profile that enables LIS-EMR integration appropriate to the constraints of resource-constrained settings.

Background

There are a number of eHealth architecture initiatives currently funded through organizations such as the Rockefeller Foundation, the World Health Organization's Health Metrics Network (HMN), the International Development Research Center (IDRC), and the Centers for Disease Control and Prevention (CDC). These initiatives provide information to support three essential eHealth architecture goals:

- A framework into which stakeholders can easily place themselves and their systems;
- A way to identify dependent and interacting components and systems within a broad framework; and
- A description of common semantic, syntactic and interaction standards or guidelines that support interoperability.[2]

The goal of interoperability--i.e., the exchange of information between two or more systems or components and the use of the information that has been exchanged--has been identified as key in connecting systems to create more integrated views of health data in support of both individual and population care. This point was emphasized in the 2008 "Making the eHealth Connection" background paper in which Bailey, et al described different types of standards required to support interoperability including: identification standards; semantic

and syntactic standards; and standards of content, such as core data sets.[3] Other important types of standards are transport protocols; security standards; and operational standards (back-up/data reliability, training, service level agreements, etc.).

In a resource-constrained environment, systems are often implemented as stand-alone products focused on specific care activities (for example, delivering antiretroviral therapy). As such, in many countries, taking a generalized approach to linking EMRs with LISs is an important area in which to achieve interoperability. As important as data standards are, we propose that it is equally important to specify "interaction standards", or standards that describe the specific information flows between the dependent and interacting components and systems whose identification comprises the second goal of eHealth architecture. These standards are written around the business rules that govern the flow of information, and describe the constraints upon, and usage of, semantic, syntactic, and other standards to support specific transactions.

Here we propose a method that provides concrete implementation guidance with a scenario of use contextualized in a resource-constrained setting. This methodology is based on our work in the Integrating the Health Enterprise (IHE) Showcase [4] as well as in Haiti and Côte d'Ivoire where we have implemented two open-source projects—the iSante EMR [5] and OpenELIS system [6] in over 55 sites—experience which has provided an excellent testbed in which to explore generalized, standards-based interoperability between these two representative systems. In addition, our goal is to use this reference implementation for Lab-EMR interoperability to support more general interoperability between other systems, such as the Bika LIS[1] and OpenMRS EMR[2].

Methods

The IHE Initiative[3] aims to improve interoperability of healthcare information systems by promoting the adoption and use of existing healthcare information technology (IT) standards. IHE provides a framework through which existing healthcare standards are applied in a structured and consistent way to address specific needs in healthcare operations, care and treatment, research, and public health. The Technical Framework presented by the organization is something similar to an integration guide describing interactions between systems. The IHEs Integration Profiles use this framework and expand it by identifying actors and transactions to address information needs that occur with specific use cases. While the IHE profiles support interoperability between a wide variety of sophisticated commercial systems, resource-constrained settings present different challenges and require an approach that addresses these challenges as presented below.

Fewer Clinical Systems and Number of Tests

In resource-constrained countries there are typically only a handful of different clinical information systems implemented and they tend to focus on specific populations, such as people living with AIDS. This presents both a benefit and a risk: the benefit is that there are fewer partners with whom one must interact to achieve develop consensus on interoperability, the risk is that partners face a constant temptation to build ad hoc linkages between the systems with which they work, rather than addressing interoperability in a more general way. We have found that we have to work conscientiously to engage other partners, and have set as a goal that our initial interoperability profile fits within the work processes and system architecture of at least two different EMRs communicating with at least two LISs.

Clinical laboratories in many resource-constrained countries have a narrower range of tests available than that which might be found in a US or European laboratory. For example, a third-party index intended to facilitate the interpretation of lab results commonly available through clinical laboratories in the USA lists over 1000 separate studies[4] yet our experience in Haiti suggests that a typical clinical lab in those settings may have a catalog of approximately 120 studies. This difference may be significant and affect the priorities when implementing interoperable systems.

Challenges in Implementing IHE Profiles

While IHE profiles are built on the real-world standards in use in health information systems which tend to be complex and use HL7 2.x messages; but the complexity of HL7, as well as the financial cost of joining the organization and accessing the standards, have limited utilization by developers working with limited resources. Since IHE profiles make use of the richness of HL7 and other standards, they inherit that complexity which presents an additional barrier to profile use in some settings.

In the laboratory domain, Logical Observation Identifiers Names and Codes (LOINC)[5] provides a semantic standard with a set of universal codes and names to identify laboratory and other clinical observations. LOINC is an open standard, however, the size and richness of LOINC may be daunting to some. Our observation has been that systems like Bluebird[6] tend to develop their own tailored specifications for exchanging data, often in XML, and often using locally developed code sets. Our experience has been similar; two large HIV observational cohort projects in which we are involved similarly use local code sets agreed upon by the participating institutions.

As mentioned in the Introduction, it is common to see stand-alone systems implemented in resource-constrained settings so linking EMRs with LISs is an important area in which to achieve interoperability—especially since the need for such linkages for reporting purposes is strong.

Documents or Messages

IHE offers both document- and message-based protocols. In the clinical domain, the former are based on variants of the HL7 Clinical Document Architecture (CDA), and include ways of exchanging medical summaries, lab results, immunization summaries, and other structured documents. Given ad hoc profiles often seem to be developed using short objects, structured using XML, we were initially tempted to use an IHE profile as the basis of our EMR-LIS interface. We explored XDS-Lab which we had used in other IHE demonstrations of public health capabilities [4] however, after consultation with other collaborators working on EMRs for resource-constrained settings, we elected to use a message model, using HL7 2.x as the syntactic standard.

At first glance, message- and document-based systems appear to be substantially different, with messages tailored to convey a stream of events that must be assembled to reconstruct the current "state" of a patient and documents able to capture a rich "snapshot" of patients. However, this is more a function of the level of information traditionally included in the syntax standards commonly used for each of these modes, rather than innate characteristics. In essence, if one takes a message, and prints it out, it becomes a document, regardless of its content, with all of the attributes of that type of artifact. And if one takes a document and carries it across the room or from the clinic to the lab next door, it becomes a message.

Developing a Resource-Constrained Appropriate Profile

To develop the resource-constrained EMR-LIS profile, we first identified the important components (see Figure 1 for acronyms and definitions) and the order in which they are utilized. The "traditional" order is as follows:

1. Patient Identification: Based on the PIX and PDQ IHE profiles.
2. Order Transmission: Based on the LSWF IHE profile.
3. Results Transmission: Based on the LSWF IHE profile.

PIX - Patient Identifier Cross Referencing - cross-references patient identifiers between organizations

PDQ - Patient Demographics Query - allows for query of a central server for demographic and visit information on a patient

LSWF - Laboratory Scheduled Workflow - establishes the continuity and integrity of clinical laboratory testing and observation data throughout the healthcare enterprise.

XD*-LAB – Sharing Laboratory Reports - a clinical laboratory report as an electronic document,

XDS - Cross Enterprise Document Sharing – allows for registry and location of documents between organizations

Figure 1- IHE Profiles of interest [7]

However, in resource-constrained settings, the first two steps are often paper-based—therefore the value of a profile is concentrated in what is traditionally the final step, Results Transmission. Because labs have needs beyond the receipt of orders and delivery of results, including quality assurance, reporting of laboratory performance indicators, and communication of inventory for supply-chain management, we believe that laboratory needs are best addressed through implementation of a laboratory information system, interoperable with an EMR, rather than the extension of the EMR to include a "laboratory module". In addition, we wanted to develop a reference implementation for Lab-EMR interoperability and to use that implementation to support more general interoperability between systems.

To accommodate the reality of the environmental constraints, we addressed these components in the following order, reverse from the order in which they occur in a typical workflow:

1. Results Transmission Only
2. Order Transmission and Results Transmission
3. Identification of Patients in EMR, Order Transmission and Results Transmission

The information interactions required to support the three use cases were assigned to specific parts of the Laboratory Testing Workflow (LTW) as described in the IHE Laboratory Technical Framework, Vol. 1: Profiles.[7] Next, the specific "actors" in those use cases were assigned to either the EMR or LIS, a constraint that further simplified the IHE profiles. Finally, the message specifications were reviewed to determine if additional simplifications could be made.

Results

The context within which we composed the profile assumed the following scenario of use that we found to be common in our work in countries like Haiti and Côte d'Ivoire.

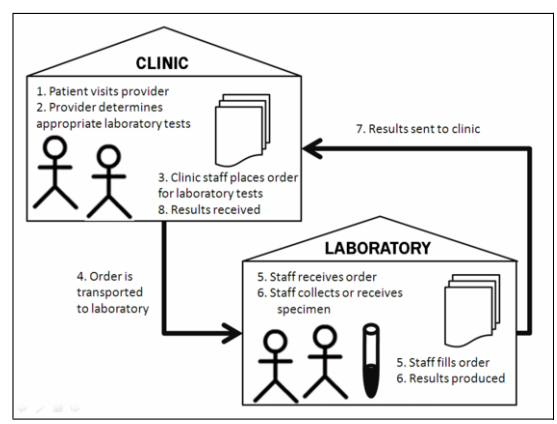

Figure 2- Lab-EMR integration scenario of use

In the clinic, a patient visits a provider, appropriate laboratory tests are identified and orders for the lab tests are placed. The order is transported to the laboratory. In the laboratory, staff receive an order, specimens are collected or received, tests are performed/orders are filled and results are produced and reported/sent to the clinic. Back in the clinic the results are received. Of note is that in the settings we are addressing, one, several, or none of these steps may involve electronic systems and when systems exists, connections may exist with similar inconsistency.

Figure 2 depicts this resource-constrained scenario of use. As stated, we are focusing first on the Results Transmission step (Step 7 in Figure 2), as the glue between an EMR and LIS. In this way, we are not only addressing the principal gap of interdependency between these two systems but we are also creating a business case for further development and funding to design and implement an LIS-EMR integrated system.

Use Case Actors and Workflow

IHE profiles define actors in terms of their roles, but in this profile, we can further assign the roles played by the use case actors to the two systems in use, with the EMR as the "Order Placer" and the LIS as the "Order Filler". The EMR also acts as the "Order Result Tracker".[7] We were able to tailor the representative workflow described in the IHE profile using both fewer potential actors as well as more limited information interactions, in order to support a more constrained set of workflows. This allowed us to limit the message types required for implementation.

The criteria used throughout this process ensured that the interactions described were part of the IHE document structure, could be referenced specifically to sections of those documents, and included only those elements of the profile which were needed to support interoperability using HL7 2.x messages between the two types of facility level systems, LIS and EMRs.

Final Profile and Scenario of Use

In the context of the LTW Profile, our resource-constrained scenario of use includes an order that is created by the laboratory and specimens which are assumed to be collected by the lab or ward, i.e.:

- Filler creates Order Filler Number
- Results transmitted post validation to the Order Result Tracker

We extended the case above to include transmission of orders, with demographics, from the EMR to the LIS. However, this does not include the ability for the LIS to query the EMR for demographics and resolve LIS patients to new or changed patients in the EMR. Therefore, we added the Patient Identification in the EMR component which both addresses this need and simplifies the cycle described. For this step, orders are placed with specimens identified by a third party and transmitted electronically. The result is that the LIS will gain the ability to query an EMR for patient demographic information, with the EMR playing the role of a Master Patient Index (MPI) component.

This profile encompasses demographics, orders and results, which are generalizable components of other information interactions. Related and potential extensions of this profile as tailored to a resource-constrained environment includes pharmacy, which is a very close match, as well as patient lookups for remote patient list management, remote sample entry, linkages to demographic surveillance systems, and other applications.

Discussion

The resource-constrained profile we present is limited in its focus primarily on transmission of results and in its assumptions. Although we believe that there is value in approaching this problem of integration stepwise, we also acknowledge the significance to all parts of the process, the issue of patient identifiers and patient matching. Patient identification presents challenges in any setting, for example there is no way for the lab to know for certain that the patient has been identified accurately. In this case, the EMR will need to be enhanced to both match on more than one identifier and to put questionable results in a queue for manual matching. Where connectivity between the LIS and EMR is intermittent, this scenario may occur fairly frequently.

We anticipate that developing an appropriate matching scheme in this case will likely need to be based on an exact match of the Patient Medical Record Number transmitted with the paper order or patient, in combination with some secondary identifiers as a double check (for example, last name, ordering facility/physician, age/Date of Birth, visit date, lab entry in the EMR). Some of the challenges of this case include: 1) There is no guarantee that a visit will have been entered in the EMR by the time the result comes back from the LIS; 2) Some (or many) patients may not be able to provide a date of birth; and 3) The ordering physician may not be part of the workflow for a particular site. For these reasons and others, it may be necessary to leave the choice of secondary identifiers for automated assignment of results in this profile to be determined on the institutional level. However, we believe that this queued matching is important in resource-constrained settings as even interoperable systems should avoid mutual dependence.

Alternatively, a purely manual system, with a strategy for catch-up when an interface is restored, must be developed. Direct entry of imperfect match results into the EMR would be a suitable strategy, and may be a reasonable alternative for manual matching and entry of results, as above.

Although insights into this interoperability profile have the benefit of being informed by our work in many resource-constrained countries, there is no way of knowing without a formal evaluation how generalizable a profile such as the one presented here would be to a wider set of EMR and LIS implementations. Future work includes such an evaluation, as well as a demonstration of this profile, in order to gather input from a wide audience of developers working in similar settings.

Abstract

Patient online eVisits are gaining momentum due to increasing consumer demand for improved access to clinical services, availability of new technologies to deploy such services and development of reimbursement initiatives by major payers. The eVisit service provides patients with an online consultation through a series of structured, secure message exchanges with a physician, providing an alternative for onsite office visits and non-reimbursed phone-based care. In this study, we evaluate a pilot deployment of eVisits in a primary care clinic providing online consultation service for 7 simple health conditions at its three locations. We examine usage data over 3 months and survey and interview results for trends in adoption, demographic and temporal patterns of usage, clinician and patient expectations and experiences, and challenges to sustainability of the service. Based on our analysis, we conclude that the eVisit pilot was a success. Patients valued the new service being offered as demonstrated by a rapid increase in usage. The quality of service was good with fast turnaround times and few exchanges to resolve a request. These positive outcomes combined with a reimbursement model are promising indications of sustainability but several challenges remain.

Patient portal, Online consult, Adoption trends, Usage analysis.

Introduction

With secure internet transactions providing standard offerings in many industries and progressing to over 50% of online users in industries like financial services, the healthcare delivery sector is seeking to leverage deployment of the electronic medical record (EMR) to provide improved customer service and market differentiators to consumers by supporting appropriate levels of care in a secure, online environment [1, 2]. Patient health portals are becoming a critical part of a healthcare organization's service delivery strategy [3]. While the EMR facilitates access to patient health information for providers and caregivers to make informed decisions at the point of care, health portals empower patients to access their clinical information and interact with their healthcare team. It allows patients to take a more active role in their own health by providing secure and convenient electronic access to their own health information [4].

Patient portals provide value to the healthcare organization by streamlining workflow, empowering the patient, and creating new communication pathways [5]. Through patient portals, users have the ability to self-service and research their own health information and health issues. By providing them with access, they can review and validate portions of their medical record. Interactions with the office also become more user-friendly and efficient. Requests for prescription refills, appointments, medical advice such as appropriate medication use, and other related information can be received electronically, automatically routed to the correct resource, and managed in a timely fashion that integrates into workflow with minimal disruption to the patient or staff [6]. Properly leveraged, patient portals can also be a valuable tool for an organization to inform patients of services and resources. Health reminders can be automatically and safely sent to patients reminding them of upcoming appointments, the need to schedule for an appointment like an annual physical or flu shot, or inform them of a new service available from the organization [7].

Perhaps one of the most valuable capabilities of patient portals is the ability to provide services to treat patients for non-urgent health conditions [6, 7]. This offering provides patients with the ability to complete and submit basic information for designated non-urgent episodic illnesses and receive an online evaluation from their physician, providing convenient, timely, and comprehensive access to care. Furthermore, this approach can evolve into a service that assists patients in managing chronic health conditions. By providing the tools to enter data such as blood glucose levels, weight, and blood pressure, and resources needed to monitor and control their health conditions over time, patients have an improved ability to actively participate in their health care and achieve more favorable health outcomes. Despite these perceived benefits, adoption rates have been uneven across patient groups [8].

In this study, we examine adoption and use by analyzing data from a pilot eVisit project implemented by a major academic medical center to provide online consultation service to patients in the ambulatory care setting. The eVisit service provides patients with online consultation through a series of secure message exchanges with a physician, providing an alternative for onsite office visits and non-reimbursed phone-based care. These are distinct from email consultations because they use a structured template-driven questionnaire to capture relevant

information about the patient's acute condition. We study eVisits in a primary care clinic, covering 7 simple health conditions at its three locations. We examine actual usage data over 3 months as well as survey and interview results for trends in adoption, demographic and temporal patterns of usage, clinician and patient expectations and experiences, and challenges to sustainability of the service.

Study Setting

The e-Visit service was piloted in one primary care outpatient practice associated with a major medical center as part of its strategic plan to computerize all ambulatory services with the ambulatory electronic medical record (EMR) for clinicians and an extensive patient portal for patients. Only patients of the health system can access the portal which has been in use for four years and currently has over 8,000 patients. The portal is integrated with the ambulatory electronic health record, which allows the health care team to interact with patients through their current applications and workflow. The application utilizes the underlying technical infrastructure and solutions offered by Epic Corporation (EpicCare EMR http://www.epicsystems.com/software-clinical.php and MyChart Patient Portal http://www.epicsystems.com/software-ehealth.php). There are several options that offer a variety of services to patients.

The clinical component of the portal provides patients with the abilities to view lab results and diagnostic studies, solicit medical advice from their healthcare team (such as questions regarding a specific medication), request prescription refills, receive health maintenance reminders, request or schedule medical appointments, and more. The business component of the portal offers automated scheduling, registration and billing services that are standardized across the enterprise and integrated with the EMR. This integration allows the health system to offer patients self-service solutions for appointment scheduling, pre-registration to update select information like address and payer information and correspondence with the business office.

On August 19, 2008, the medical center released an additional function for the clinical component, called eVisits. The eVisits service provides patients with an online consultation through a series of secure message exchanges with a physician. The primary objective of this new online service is to provide an alternative for onsite office visits and reimbursable phone-based care. This eVisit system currently provides service for 7 conditions: cough, red-eye, vaginitis, diarrhea, sore throat, urinary tract infection, and back pain as well as a generic category of "other." A standardized template creates structured documentation of the consultation, is easy to use and integrated with practice workflow. It also captures information that is stored in the EMR.

This new offering was tested in Fall 2008 at a single community primary care practice encompassing three office locations. The physicians and staff at the offices encouraged patients to sign up for the patient portal and use eVisits for the treatment of specified episodic illnesses. Thus use of the service was purely voluntary. As of December 5, 2008, 126 patients had used the service and 11 physicians were participating. During the pilot phase, the eVisit service was offered at no cost to the patient.

The key stakeholders in this project are the physicians, the patients, and the insurers. The patients need to be convinced that the eVisit system can provide them with good quality of service while offering the additional convenience of accessing a physician's medical advice online. The physicians need incentives to participate in the system, primarily through reimbursement for their services, as well as providing better care. Insurers need a clear understanding of how this service is going to be implemented, and the policy and guidelines, so that it can be covered under current health plans. The success of eVisits is dependent on the buy-in from the stakeholders mentioned above.

The eVisit Process

The process is initiated by a patient who logs into the patient portal to submit an eVisit for a non-urgent health condition. The patient is introduced to information regarding eVisits, including overview, warnings, and frequently asked questions, linked to "Submit an eVisit" option as well as a video demo of an eVisit for patient education. The patient must accept the terms and conditions of eVisit comprising emergency disclaimers and privacy policy before accessing the main forms to list symptoms associated with any of the 7 conditions covered by the eVisit service (Figure 1). An 'Other' category is available to allow specification of conditions that are not included in the 7 well defined areas (Figure 2). The patient may select pharmacy for any prescriptions needed for the visit or add their own, and review health issues, medications, and allergies.

Figure 1- Screen Shot of eVisit Request Form

In the case of the 7 specific conditions, a questionnaire with branching specific to a chosen condition and related symptom is completed and free text added for symptoms not on the list. Once the eVisit is submitted, the message goes to a support staff pool, a successful message submission acknowledgement is received and the patient is notified of subsequent steps. These include forwarding the eVisit to a physician who is on call to provide a timely response during regular business hours. The physician reviews the eVisit, makes diagnosis, and replies to

the patient about how to proceed. Once the patient receives the information, and it is deemed to have addressed the health condition, a satisfaction survey is completed. If the patient has additional concerns, a few request-response exchanges take place before the physician closes the encounter and notifies the support staff. This completes the eVisit.

Figure 2- eVisit Questionnaire for 'Other' Category

Data Collection

Data for analyzing usage and trends came from several sources. These included portal activation data for eligible members of the medical center as well as the clinic participating in the pilot study, de-identified patient demographics and eVisit transaction data, patient and physician satisfaction surveys, clinician interviews, phone encounter records, and payer information. Transaction data related to eVisits submitted between August 20, 2008 and December 5, 2008 included a unique message identifier, associated eVisit, patient and physician identifiers, date, time and subject of the message (one of the 8 conditions), and whether the message was from/to the patient. Patient demographics included age, gender, ethnicity, marital and employment status. Total patient population of the study clinic and the subset who had activated portal access were also available. Overall, 152 eVisits were submitted by 126 unique patients, with 18 patients submitting requests more than once,16 patient and 11 physician satisfaction surveys were completed, and 417 total messages were exchanged between patients and physicians.

Analysis of Usage

The data described above was analyzed to examine the following patterns of usage and trends. The demographic characteristics of residents in the 3 locations of the primary care practice were quite similar. During the eVisit pilot period, the number of new portal patients increased from August to October and decreased from October to November. However, new eVisit patients kept growing from August to November. In August, only 4% of the new portal patients used eVisits. From September to November, the percentage increased to 14%, 18%, and 25%, respectively, indicating that patients were adopting the eVisits service.

Who is using it?

The clinic has a population of more than 23,000 patients, of which about 1,600 have activated portal accounts, 375 submitted medical advice requests, 152 submitted eVisits and about 1,300 received phone-based care during the pilot study period. Across all these groups, age was normally distributed. A cross-sectional study of the demographic profiles of patients drawn from these populations indicates that more than 50% of eVisit patients are between ages 36 and 55. Analyzing gender distribution among these different groups shows that in all five groups, the female population is substantially more than the male population, with women using eVisits, in particular, three times more than men.

When are they using it?

75% of the messages sent by patients initiating an eVisit were during the hours of 9am and 6pm. At the same time, 94% of physicians responded between 6am and 3pm, so physicians tended to start early in the day to catch up on messages that may have been sent the previous day by patients. Messages were evenly distributed across weekdays with very little activity on weekends. Most of the eVisit messages were responded to within the same day, however, messages sent between 3pm and 6pm were likely to be responded to on the following day. On average, patients waited about 6 hours to receive a response at any given time. During physician office hours (9am-3pm), the waiting period reduced to an average of about 3 hours, indicating a reasonably responsive turnaround time by the health system. In particular, a significant majority, 65% of all patients, received a response from a physician within the hour.

How are they using it?

A request-response pair of message exchanges between a patient and physician in an eVisit is termed a 'volley'. Volleys are an important measure of the workload associated with online consultations. As the number of messages exchanged with patients to resolve a specific health issue increases, physicians may perceive an office visit to be more fruitful. Volleys help in examining these trade-offs. Our analysis indicates that eVisits require, on average, 1.22 volleys to achieve closure on a request. Out of the 152 eVisits logged in this study, 82% were completed by physicians within 2 responses, indicating that most eVisits are fairly straightforward, and do not require patients and physicians to go back and forth several times.

Frequency of eVisits usage had some interesting aspects as well. Out of 126 unique patients, 14% submitted an eVisit request more than once. Among the conditions for which the eVisits were submitted, over 50% of patients submitted requests for the "Other" category and 25% for Sinus/Cold symptoms. Within the "Other" category, there were no significant patterns in patient conditions; however, skin related disorders, such as breast rash and skin lesions, did appear a few times more than others.

Patient Satisfaction

Patient satisfaction with the eVisit service was analyzed using surveys that were submitted by 28 patients after using an eVisit.

In general, patients were highly receptive to the service. Patients found the service to be easy to use and were satisfied with the quality of care received. 95% of patients said they valued online access to the physicians and intended to continue using eVisits again, as well as recommend it to others. The typical concerns patients voiced when informed about eVisits were around privacy and confidentiality and co-pay. Senior citizens found the concept confusing while the younger and computer savvy patients were excited about the new service.

Clinician Perceptions

11 physicians participating in the eVisits pilot deployment completed surveys after using eVisit at least once. There were 4 female physicians between the ages of 36 to 54 and 7 male physicians between the ages of 41 to 57 in the sample. Physicians were concerned about the ease of use of the interface, finding it somewhat non-intuitive and inflexible to address a diagnosis at any point during the consultation. eVisit was clearly not a preferred mode to treat patients with acute conditions. However, interviews with the physicians highlighted the value of eHealth as an important component of modern medicine with the potential to improve healthcare, increase income for organizations and be convenient for patients. Reimbursement was an important incentive for adoption and use of eVisits. Physicians considered younger and more tech-savvy patients to be the target audience for this service. Due to concerns about patients underreporting their conditions or requesting inappropriate advice online, 50% felt that face to face was a better way to diagnose. Interviews were also conducted with 3 office staff and 3 nurses involved with the service at the 3 locations of the primary care practice. Office staff alerted and educated patients about the eVisit service. They perceived that the number of phone calls had reduced since the eVisit pilot began, but this has yet to be determined quantitatively.

Analysis of Phone Encounters

One of the objectives of the eVisit pilot deployment was to estimate the potential for shifting non-reimbursable phone-based care to reimbursable online consultations. Phone encounter records over a period of 2 years were analyzed to examine the significance of this potential. From June 2006 to June 2008, there were 40,489 phone calls from patients to the three office locations of the practice. As shown in Table 1, about 10% of the calls were related to the 7 eVisit conditions. The majority of the phone calls were related to other conditions such as checking test results or requesting medication refills (portal functionality is also available to meet these requirements). Furthermore, about 18% of all calls were by portal users who were eligible to access the eVisit service. Phone encounters by these users during the eVisit pilot period, shown in Table 2, indicated the same distribution of phone calls, with about 10% of the phone calls being potential eVisits.

Table 1- Analysis of All Phone Encounters June 2006 - June 2008

	# of Phone Calls/month	**Percentage**
eVisit potential (7 conditions)	172	10%
Other Conditions	1400	83%
Inappropriate	116	7%
Total	1688	100%

Table 2- Analysis of Phone Encounters with Portal Users August 2008 – November 2008

	# of Phone Calls/month	Percentage
eVisit potential (7 conditions)	25	10%
Other Conditions	212	85%
Inappropriate	13	5%
Total	250	100%

Discussion and Conclusions

The success criteria for the pilot deployment were identified to be (1) positive perceptions regarding eVisit service including both workflow and technology experience on the part of eVisit patient and provider users; (2) increasing frequency of use in practices which marketed eVisit services; (3) documented opportunities related to translating phone encounters into reimbursable services; and, (4) accurate and thorough data and operational documentation for reimbursement analysis. On the first and second measures, while patients expressed satisfaction and value through increased use of the service over the pilot phase that was well beyond expectations, providers had some concerns about functionality and value of the service. Based on our analysis of phone-based encounters, there is some evidence that the potential exists for getting value from converting these users to eVisits. However, the total returns are clearly tied to reimbursement policies that would be eventually adopted. On the fourth measure, the implementation of the eVisit process for specific health conditions with branching logic that automatically captures date and time stamped critical documentation and treatment details and associated participant

information ensures the capability of the service to capture all the necessary data for reimbursement analysis. Thus, based on these measures, our preliminary analysis indicates that the pilot was a reasonable success.

Three distinct areas posed challenges associated with expansion of the service: 1) reimbursement model, 2) patient adoption strategies, and 3) provider adoption strategies. The medical center has implemented a reimbursement model from April 1, 2009, which is being evaluated currently. Patient education and outreach efforts combined with improved usability and innovative marketing campaigns, optimizing the triage process for providers by filtering out the inappropriate eVisit requests, demonstrating workload benefits from secure messaging, and analyzing the clinical computing workload and workflows through better interface design are additional characteristics that need to be studied.

In summary, patients appeared to see value in the new service being offered and this was demonstrated by the rapid increase in usage. The quality of service was good, with fast turnaround time and low number of messages exchanged before resolving an issue. eVisits may also prove to be of considerable valuable in post operative management and chronic care management settings, another focus of our ongoing evaluation. By further developing the portal strategy, the medical center can provide greater service to patients and improved value and competitive advantage for the organization.

Acknowledgements

We are grateful to S. Agarwal, Y. An, Y. Cho, A. Fong, A. Nayak, C. Rugege, J. Tomaino and R. Alvarado for their assistance with the data collection and analysis of the pilot study. We also thank all the physicians, administrators, and staff involved in the planning, implementation and management of this project.

Patients' Needs Assessment Documentation in Multidisciplinary Electronic Health Records

Kristiina Häyrinen, Kaija Saranto

Department of Health and Social Management, University of Eastern Finland (Kuopio Campus)

Abstract

The purpose of this study is to describe and discuss physicians' and nurses' documentation of the patient's needs assessment in electronic health records (EHR) in the neurological care setting. Both physicians and nurses collect, record and interpret data during patient care episodes. Assessment of patient's need for care and treatment is an important part of the care process. Planning, implementation and outcome assessment of the care process are based on needs assessment data. The data of this study consist of 48 neurological medical narratives and nursing care plans. The data were analyzed using descriptive statistics and content analysis. Physician's medical narratives include referrals to physiotherapy and consultations in other care specialities in which they have recorded the reason for the care, anamnesis and status praesens data. Nurses have documented patient's needs assessment in nursing care plans using Finnish Classification of Nursing Diagnoses (FiCND) and additional narrative text. Physicians' and nurses' patient needs assessment documentation complement each other. Nursing documentation includes more detailed information about patients' needs for care due the use of FiCND in documentation. The use of standardised documentation improves quality of the documentation and retrieval of data from EHR.

Keywords:

Medical records systems, Computerized, Medical informatics, Nursing informatics, Documentation

Introduction

Patient's needs assessment documentation is an important part of electronic health record (EHR) data. Documentation of the planning, implementation and evaluation of patient care is based on needs assessment documentation. Among the various health care professionals who record in EHR are physicians and nurses. The EHR include all information documented by different health care professionals during patient care episodes in health care organizations. [1,2] EHR refers here to an information repository where patient data is stored in digital form. It contains retrospective, concurrent, and prospective information and its primary purpose is to support continuing, efficient and quality integrated health care. [3]. The primary function of EHR is to support health care professionals' decision-making while providing the patient with care. The goal is patient-centered recording and use of data of EHR for co-operative care both within one health care organization among different health care professionals and between health care organizations. [1,4] According to earlier studies EHR has been noted to support collaboration and communication between health care professionals. [5-7] The aim of this study is to describe and discuss physicians' and nurses' documentation of patients' needs assessment in EHRs.

Background

Patient's needs assessment documentation in EHR

EHR includes both physicians' documentation of the assessment of patients' complaints and nurses' documentation of patients' needs assessment. Physicians' notes may include subjective symptoms expressed by the patient, physician's objective observations based on physical examination and patient's medical, family and social history. [1,8] Nurses also collect and record patient health data by discussing with and examining the patient and utilize this information while assessing the patient's needs for nursing care [1,9]. (Table 1)

In information systems physicians document patients' assessment data in problem lists e.g. [10-14] templates or forms e.g. [15-17] or data is recorded in medical narratives e.g [8,18]. Earlier research on physicians' documentation of patients' assessment of complaints has mainly focused on information quality e.g. completeness or accuracy of documentation. Earlier studies reveal that use of information systems improves the completeness of documentation. [2] Galanter et al. argue that physician documentation of the problem list is incomplete. The quality of problem lists has improved with the integration of clinical decision support into the process of medication. The system proposes that the physician should add a diagnosis to the problem list based on the prescription. [14]

Nurses' documentation of patient's needs assessment is in nursing care plans. Earlier studies have shown a lack of notes on needs assessments including nursing diagnosis e.g. [19-20]. However, the inclusion of nursing diagnoses has been shown to improve the quality of patients' needs assessment

documentation, and the quality of nursing interventions and the outcomes of nursing interventions. Although deficiencies were found in the documentation of signs and symptoms. [21]

Bakken et al. (1995) has compared physicians', nurses' and patients' problem list between each other. Each patient has problem that occurred on more than one problem list. Problems which occurred only on nurses' problem lists were knowledge deficit and potential for injury. Nurses' problem lists provided additional significant information related to patient status that had the potential to affect patient outcomes. [13]

The unified content of EHR

In a national EHR development project in Finland the content of EHR was developed and unified. The core data elements and headings were defined [22]. The core data elements of EHR include patient identification information, the provider's identification information, care episode, risk factors, health patterns, vital signs, health problems and diagnosis, nursing minimum data set, surgical procedures, tests and examinations, information about medication, preventive measures, medical statements, functional status, technical aids, living will, tissue donor will, discharge summary, follow-up care plan and consent information. The documentation of the core data requires the use of vocabularies, nomenclatures and classifications. [23] Classification of Diseases and Related Health Problems (ICD 10) which is based on the WHO International Statistical Classification of Diseases and Related Health Problems is used in the documentation of medical diagnoses in specialized care. Surgical procedures are recorded using the NOMESCO Classification of Surgical Procedures. The Nursing Minimum Data Set includes information on the nursing diagnosis, interventions, outcomes, intensity and discharge summary. Nursing diagnoses and aims for care are documented according to the Finnish Classification of Nursing Diagnoses (FiCND). The Finnish Nursing Classification is based heavily on Clinical Care Classification e.g. [24].

The headings are almost the same as the core data elements supplemented with items such as reason for care, anamnesis or status praesens under which physicians record mainly narrative text.

The unified content of EHR also fulfills legislative demands. According to the Finnish legislation, each health care organization must create a cumulative patient record, which must include necessary and sufficiency information on patient care: reason for care, history, status, findings, tests, problems, diagnosis, health risk, conclusions, planning, delivering and assessment of patient care, progress notes and discharge summary for each care episode. [25]

Both physicians and nurses document patients' needs assessment information as free text in their own words and using, headings and classifications (Table 1).

Table 1 – Needs assessment documentation by physicians and nurses

	Free text	Use of headings	Use of classifications
Physician	Descriptions of subjective complaints as expressed by the patient and the findings of physicians, medical, social and family history	Reason for care Anamnesis Status praesens	Initial diagnoses (ICD 10)
Nurse	Descriptions of patients' signs and symptoms	Nursing diagnoses	Nursing diagnoses (FiCND)

Materials and Methods

The site for this research was a central hospital in Finland using an EHR system since 2000 and a nursing care plan component since 2004 in neurological care. An electronic health record comprises several data components (Figure 1). Data collection in this study was from anonymous medical narratives, nursing care plans and administrative data components in neurological care. The director of the Hospital District approved the study.

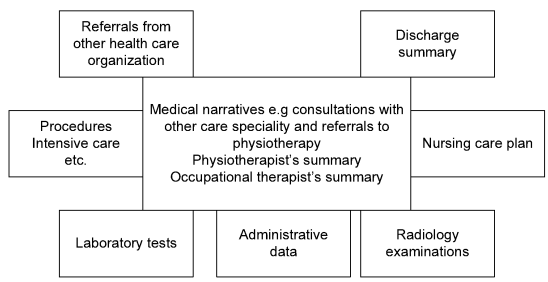

Figure 1- Data components of EHR

The Finnish Classification of Nursing Interventions (FiCNI 1.1), FiCND 1.0, ICD 10 and Classification of Surgical Procedures were implemented in an EHR system. The nurses did the documentation according to the national nursing documentation model based on the WHO nursing documentation model and use of Finnish Nursing Classifications [26]. Physicians may make entries themselves in the EHR system or dictate their documentation to be transcribed by audiotypists.

The data consist of 48 inpatient patient nursing care plans and physicians' medical narratives including consultations with other care specialities and referrals to physiotherapy. The duration of care episodes was from 6 to 127 days (mean 45). The nurses updated 11 patient's nursing care plans during care

episodes once or more frequently. The nurses recorded in almost all nursing care plans admission notes such as reason for care (n=44) and from where patient was admitted to the ward (n=43). Most of the patients (n=37) arrived from other wards or from the emergency department (n=3) of the hospital. Furthermore, one patient arrived from a university hospital. Some patients (n=2) had appointments for treatment. Physicians' documentation included consultations with different specialities (n=37) and referrals to physiotherapy (n= 46). The physicians documented 1-8 consultations with other care speciality or referrals to physiotherapy per patient. Mainly (n=38) physicians' documentation included only referrals to physiotherapy.

The frequencies of the nursing diagnoses were calculated. Physicians' medical narratives were first analyzed using deductive content analysis and categorized according national core data elements and headings. Secondly, frequencies of headings and data elements were calculated. The data were analyzed using statistical software SPSS® 14.0 (Statistical Package for the Social Sciences; SPSS Inc., Chicago, IL, USA).

Results

Nurse's needs assessment documentation

The nurses assessed each patient's need for care and recorded nursing diagnoses mainly using FiCND and complementary narrative text. Only in two patient's nursing care plan were nursing diagnoses documented using only narrative text. The nurses documented 2-17 nursing diagnoses per patient in the nursing care plans (mean 9).

Nursing diagnoses were documented mainly using FiCDN major categories or subcategories. All Care Components of FiCND except "Health services" were used in the documentation of nursing diagnoses. Nursing diagnoses were documented more frequently using "Self care", "Activity" and "Elimination" Care Components of FiCND. In table 2 is shown frequencies of different Care Components and major and subcategories of frequently used "Self care" and "Activity" Care Components. (Table 2) Inability to carry out activities of daily living were deficits in self care e.g impaired ability to perform ablutions alone, impaired ability to dress and tidy oneself, impaired ability to eat unaided or impaired ability to urinate or defecate unaided. The deficits of activity were changes in patient's physical or functional actions which were related his illness. The patients' elimination needs of nursing care include urinary and bowel incontinence.

Table 2 – Nursing diagnoses for 48 patients (N=407)

Care Component	Major/sub category	n	N	%

Physician's documentation

Physicians' medical narratives (n=83) included referrals to physiotherapists and consultations with other medical specialty e.g. surgery. These notes also included patient assessment documentation. Medical narratives were stored mainly as free

text. Only diagnoses (n=6) and surgical procedures (n=3) were documented using classifications in consultations with other medical specialties. ICD 10 was used in diagnosis and the NOMESCO Classification of Surgical Procedures in surgical procedures documentation. Notes were structured using headings in six patients' documentation. Physicians recorded reason for care, anamnesis and status praesens in referrals to physiotherapy or to other care specialties. (Table 3)

Table 3 – Documentation in physicians' medical narratives for 48 patients (n =83)

Headings	Data Element	n	%
Reason for care		27	32
Anamnes		46	55
	Laboratory test	2	
	Radiology	11	
	Medication	8	
	Functional status	23	
	Surgical procedures	15	
	Health patterns	3	
	Technical aids	6	
	Vital signs	8	
Status praesens		46	55
	Laboratory	3	
	Radiology	11	
	Medication	1	
	Functional status	29	
	Technical aids	2	
	Risk factors	1	
	Vital signs	9	

The reason for care was documented in 27 physicians' notes. Both anamnesis and status praesens information were documented in 46 physicians' notes. Anamnesis and status praesens information included information from laboratory or radiology tests, likewise on medication, functional status, technical aids and vital signs. Furthermore, anamnesis included information on surgical procedures, health patterns and status praesens documentation described risk factors. (Table 3) Physician documentation of patient's functional status described patient's problems in physical or functional actions related to medical diagnosis.

Both in physicians' and in nurses' notes more frequently described patients' inabilities to carry out activities of daily living and deficits in activity.

Discussion

The aim of the study was to describe and discuss physicians' and nurses' patient's needs assessment documentation in EHRs. The results indicate that both physicians and nurses had documented needs for patient care and treatment in their own documentation. Nurses mainly described patients' needs for care using the nursing diagnosis classification (FiCND). Nursing diagnoses represent patient problems requiring clinical care by nurses. The most used Care Components of FiCND were Self Care and Activity, which describe the functional health pattern of clinical care in nursing practice. It is obvious that these health patterns emerge in neurological patient nursing documentation. Nurses' documentation also included admission notes such as reason for care and arrival information. In Finland this is obligatory information for national statistics and perhaps therefore nurses also recorded these items. Thus the information on reason for care in nursing care plans include information which partially overlaps what is documented in physicians' medical narratives e.g. in anamnesis documentation and the information is related in medical diagnosis.

Physicians' medical narratives include referrals to physiotherapy and consultations with other treatment specialities. These notes include information on the reason for care, patients' subjective complaints and physicians' objective findings. Data retrieval of patients' problems could be easier if physicians' documentation of patients' problems were separately e.g. in a problem list rather than in medical narratives. Furthermore, the use of the structured and coded core data elements of the EHRs also facilitates e.g problem linked with free text. The use of classifications or structuring notes with headings in documentation could improve the completeness of patient records and data retrieval from patient records. [8,12]

Both nurses' and physicians' documentation described patient's problems in physical and functional actions. Bakken et al. (1995) has also noted that the same problems occurred in nurses' and physicians' documentation and these problems are related to medical diagnoses. Thus nurses' documentation used the FiCND and this documentation provided detailed descriptions information on patients' problems.

The use of the other health care professionals' documentation is necessary in patient care during care episodes. This study shows that nurses and physicians must also know where they can find other health care professionals' notes. It is remarkable that physicians' only notes recorded during care episodes are about consultations with other care specialities and referrals to physiotherapy. This may be due the use of paper notes in parallel: physicians utilize these paper notes while recording the discharge summary at the end of the care episode.

Conclusion

Both physicians and nurses record needs assessment data regarding patient care and treatment. Nurses' documentation is more detailed than physicians' documentation. Physicians' notes are narrative text, and due to this it is difficult to locate information. The use of standardised documentation would improve the quality of the documentation and retrieval of data from EHR.

Abstract

Computerized documentation methods in Intensive Care Units (ICUs) may assist Health Care Providers (HCP) with their documentation workload, but evaluating impacts remains problematic. A Critical Care clinical Information System (CCIS) is an electronic charting tool designed for ICUs that may fit seamlessly into HCP work. Observers followed ICU nurses and physicians in two ICUs in Edmonton, Canada, in which a CCIS had recently been introduced. Observers recorded amounts of time HCPs spent on documentation related tasks, interruptions encountered by HCPs, and contextual information in field notes. Interruption rates varied depending on the charting medium used, with physicians being interrupted less frequently when performing documentation tasks using the CCIS, than when performing documentation tasks using other methods. In contrast, nurses were interrupted more frequently when charting using the CCIS than when using other methods. Interruption rates coupled with qualitative observations suggest that physicians utilize strategies to avoid interruptions if interfaces for entering textual notes are not well adapted to interruption-rich environments such as ICUs. Potential improvements are discussed such that systems like the CCIS may better integrate into ICU work.

Intensive care, Clinical information systems, Interruption, Time and motion study

Introduction

Health Care Providers (HCPs) working in Intensive Care Units (ICUs) attend to highly acute and complex patients. Effective care requires continuous monitoring by specialized and costly HCPs. Coordinated care among different HCPs and over time is called continuity of care and is a central determinant of patient outcome [1-3]. Continuity of care depends on the communication of patient condition changes and care plans to pertinent care team members, frequently using patient charts. Information contained within patient charts is vital for decision making, and ideally should be current, complete, and correct.

One approach aimed at assisting HCPs working in ICUs with their documentation workload uses computerized clinical information systems. A Critical Care clinical Information System (CCIS) is designed to replace paper charts and interface with ICU bedside equipment and laboratory systems to automate some documentation tasks for HCPs [4]. It is believed that a CCIS may aid communication among HCPs but little evidence currently exists.

This paper reports part of a larger project evaluating whether a CCIS in two ICUs in Edmonton, Canada is beneficial for patient care [5]. Trained observers followed physicians and nurses to record the amount of time spent on documentation related tasks and numbers of interruptions HCPs encountered while going about their work. Needs for timely communication in environments such as ICUs and emergency departments result in HCPs interrupting and being interrupted more frequently than in other hospital environments [6,7]. Rates of adverse medical events in ICUs are more frequent than in other hospital wards [8]. Interventions aimed at reducing error, along with more methodologically sound research investigating relationships between medical error and work interruptions, are needed [9,10].

To formulate effective plans to manage and reduce the consequences of interruptions recent work has investigated reasons HCPs initiate interruptions in high acuity health care settings [11]. Interruption recipients may block or delay interruptions [12] suggesting that recipients can take an active role in prioritizing interruptive communication patterns above or below their current or 'primary' task [13]. HCPs are likely to prioritize patient care tasks above documentation tasks [14]. We suggest that interruption rates during documentation tasks may provide a measure of the extent to which this prioritization occurs.

We report interruption rates during documentation tasks for nurses and physicians in two ICUs before and three months after the introduction of a CCIS. The findings are discussed with reference to frequent types of documentation completed by nurses and physicians. The results demonstrate needs for more interruption tolerant data entry mechanisms in ICUs and emergency departments.

Methods

Setting & Participants

The University of Alberta Human Research Ethics Board approved this study prior to data collection. The study was conducted at the Pediatric ICU (PICU) at the Stollery Children's Hospital and the General Systems ICU (GSICU) at the University Hospital, both in Edmonton, Alberta, Canada. Both are located within busy academic tertiary referral hospitals. The PICU has 17 beds. GSICU has 30 beds with 24 operational due to staff shortages. Laboratory results are accessed with computers at nursing stations and throughout the unit. The ratio of patients to nurses is 1:1 in PICU. In GSICU, the patient to nurse ratio is 1:1 70% of the time and 2:1 30% of the time depending on patient acuity.

Staff members were informed of our study with presentations given by the research team, and with posters distributed around the units. Research team members approached nurses and physicians to obtain their consent to be observed. Of 215 nurses in permanent staff positions, 97 agreed to participate. Of 36 physicians, 34 agreed to participate. Chief residents and sub-specialty fellows were included in the group of observed physicians.

Observations

Observers were trained for at least 12 hours prior to conducting observations. In training sessions, trainees were paired with experienced observers to observe and score a single participant. Inter-rater reliability scores were then calculated from the reported amounts of time spent on the task categories. Observers conducted their own observations after obtaining inter-rater reliability scores above 85%. Observations were conducted for a maximum of 90 minutes without advance notice to participants. Equal numbers of nurse observations were conducted during mid-day (07:00-19:00), mid-night (19:00-07:00), morning shift change (06:30-08:00), and evening shift change (18:30-20:00). Physician observations were conducted during morning rounds (08:00-12:00), sign-out rounds (16:00-17:00), and at night rounds (20:00-00:00). Observers kept field notes recording how busy units appeared, whether students were present, and contextual information to help with interpreting observational data. Observations were suspended if participants left the unit.

Baseline observations were conducted between September and November 2008 in PICU, and between January and February 2009 in GSICU. The CCIS was introduced to the GSICU and PICU in March, 2009. Once connected, patient vital signs were automatically recorded in charts. Lab results, ventilators and dialysis machines did not interface with the system at the time of observation. Medication orders were handled with paper records. Post-CCIS observations were conducted between May and June 2009 in both units. Before the system was introduced, 57 hours of physician observations and 60 hours of nurse observations were conducted. After the introduction, 50 hours of physician observation and 56 hours of nurse observations were completed.

PDA Data Collection Tool and Work Definitions

The WOMBAT software runs on Hewlett-Packard iPAQ hx2490 or 110s [15]. Time stamped data was extracted into Excel spreadsheets via a laptop computer. Westbrook and colleagues provided detailed task definitions which we refined to include tasks specific to the observed units [16]. Observers carried the paper work definitions to assist in recording the tasks observed into PDA categories. Documentation tasks were scored when participants wrote or typed in information into permanent records, CCIS, other computer applications, or other paper. The complete definitions are described elsewhere [16]. Observers recorded the medium using the WOMBAT software. Interruptions were also recorded using the WOMBAT software if any external factor (e. g., an alarm, another care provider, a patient) appeared to cause the participant to cease their task and perform a secondary task [15].

Statistics

Interruption rates and proportions of time spent on documentation tasks were calculated for observations. Interruption rates when completing documentation tasks using the CCIS and other Non-CCIS methods (permanent records, paper, or other computer applications) were compared using t-tests assuming unequal variances. The significance level was set at 0.05.

Results

Amount of time spent on documentation tasks

During our observations, physicians spent 15.2% of their time (mean, +/- 5.3%; 95% Confidence Interval) and nurses 26.4% (+/- 3.1%) performing documentation tasks before the CCIS introduction (Figure 1A). After the CCIS implementation, both physicians and nurses used CCIS and non-CCIS methods of completing documentation tasks. The percentage of time spent on documentation tasks while using the CCIS was 1.6% (+/- 1.9%) for physicians and 14.8% (+/- 3.2%) for ICU nurses. The time spent on documentation tasks after the CCIS introduction using Non-CCIS methods was 7.3% (+/- 2.8%) for physicians and 5.7% (+/- 1.8%) for nurses.

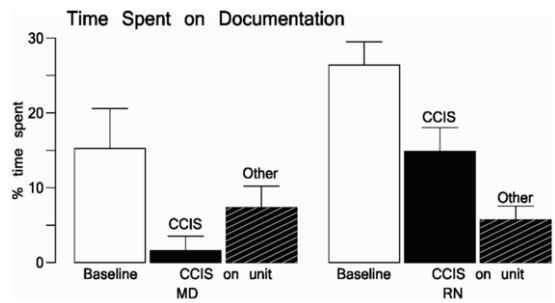

Figure 1- Mean percentages of time spent on documentation tasks before the CCIS and after by ICU physicians and nurses using the CCIS or Non-CCIS media (+/- 95% Confidence Intervals).

Interruptions during documentation tasks

Before the CCIS introduction, the rate of interruption during documentation tasks was 2.2 (+/- 1.4) interruptions per hour for physicians and 4.5 hr^{-1} (+/- 1.9) for nurses (Figure 1B). When physicians performed documentation tasks using the CCIS the interruption rate was 0.35 hr^{-1}(+/- 0.45). Physicians were interrupted significantly more often when documenting with Non-CCIS methods, at a rate of 4.0 hr^{-1}(+/- 3.4). After the CCIS introduction, nurses were interrupted at a rate of 8.8 hr^{-1} (+/- 3.5), which is significantly more often than when performing documentation tasks using Non CCIS methods (1.4 hr^{-1}; +/- 1.2).

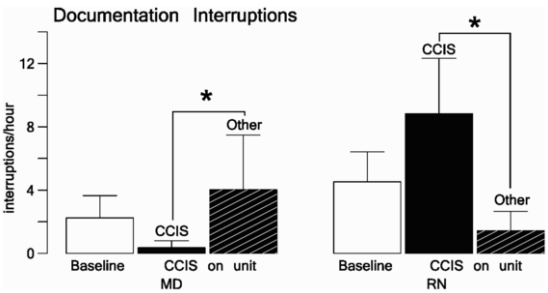

Figure 2- Mean interruption rates during documentation tasks observed before and after the CCIS introduction for ICU physicians and nurses. Interruption rates for documentation tasks were determined based on the media used, the CCIS itself or Non-CCIS media (=p<0.05)*

Discussion

The results identify role specific changes in interruption rates during documentation tasks depending on the media HCPs use after a CCIS introduction. In the two ICUs studied, physicians spent more time documenting care using Non-CCIS methods than they did using the CCIS after the CCIS introduction. When physicians performed documentation tasks using the CCIS, these tasks frequently consisted of long notes. If physicians were interrupted while writing notes, the session could time out due to inactivity. When the physician returned, they would spend additional time amending their note. As 'copy' and 'paste' functionalities were unavailable using this system, physicians would often need to rewrite the note completely.

Strategies used were documented by observers with field notes. For example, an observer noticed a senior physician approach a trainee to initiate a conversation. The senior physician first confirmed that the trainee was not busy writing a note in the CCIS before they continued their conversation. In another incident a physician accepted a newly admitted patient following a surgery. Once the immediate task of receiving the verbal information from the surgeons and providing orders to the care team was complete, the physician moved to an unused terminal at some distance from the patient to enter a note into the CCIS. In other instances, observers noted some nurses remarking that physicians using the CCIS could be less responsive to requests than when completing other tasks. Based on these observations, ICU physicians may attempt to reduce the likelihood of being interrupted when they use the CCIS. Strategies may include deferring communications to later times, or performing documentation tasks in locations more distant than using paper charts. The observational data are consistent with this as ICU physicians performing documentation tasks using the CCIS were interrupted less frequently than when using Non-CCIS documentation methods.

A contrasting situation exists for nurses completing documentation tasks using the CCIS. The observational data show that nurses were interrupted more frequently when performing documentation tasks using the CCIS than when using Non-CCIS methods. The increased rate of interruption during CCIS documentation tasks likely has causes and effects that are not yet identified. The workload associated with nursing care requires that nurses spend large proportions of their time at the bedside or at nursing stations near patients. Nurses may not have the same degree of flexibility to employ strategies that physicians use in deferring interruptions. Alternatively, nurses completing documentation tasks with the CCIS may be able to resume with less disruption compared with physicians. Nurses are discouraged from entering text notes into the CCIS. The increased rate of interruption could be accounted for if nurses have less incentive to delay or block interruptions.

Significance

These findings may have implications for patient care provided in ICUs. One implication involves physician availability. HCPs value the convenience of being able to perform documentation tasks and review chart information remotely rather than at the bedside [17]. For some classes of information, such as lab results, physicians may more easily obtain current information at an unoccupied computer than at the bedside. Physicians accessing chart information remotely may be able to make better decisions about when they need to come to the bedside.

Care providers working at the bedside will typically prioritize patient care above documentation tasks [14]. Data entered into the chart about procedures performed and assessments of patient status may not be completely updated, depending on workload. If physicians choosing to work remotely so as to avoid interruptions during documentation tasks tend to spend less time on the unit, there is the potential for subtle reductions in physician availability to come about as an unintended consequence of introducing clinical information systems such as the CCIS. We posit that the inability of the CCIS to pause and later resume note entry represents a potential area of improvement for a system designed for the critical care environment.

Potential Solutions

One solution might involve physicians adopting documentation methods much like other HCP roles, where text entry is discouraged. Difficulties with this approach surround the complexities of medical documentation. Most physicians are trained to write text notes that are human readable rather than completing their documentation tasks using other data entry

mechanisms including drop-down boxes. As a result, physicians may resist this option.

A second potential solution involves enabling copy-paste functionality. Recent work has investigated some of the unintended consequences that can result when physicians use copy and paste functions [18]. Some of these consequences include the potential for notes from previous days to be brought forward inappropriately and thus fail to track changes in a patient's progress over time. Investigations into physicians' attitudes toward and usage of copy and paste functions from other hospitals where these functions are enabled in documentation tools have shown that physicians report that they value these functions to keep up with burgeoning workloads [19]. The percentage of time physicians in our study spend using the CCIS is highly suggestive that senior physicians tend not to use this system to complete their documentation tasks, but may delegate CCIS documentation tasks to more junior physicians, and resort to more flexible methods. These methods include using paper and other software including word processors where copy and paste functions are available. Although not including these copy and paste functions may avoid the potential unintended consequences described above, it may also severely limit the utility of the CCIS to physicians. Appropriate physician training regarding potential issues around the use of copy and paste functions could be included in medical school curricula, residency training, and continuing medical education, such that systems like the CCIS provide better utility to physicians.

Third, the system could save a partially entered note as a 'draft' when locking out a user. Other care providers could view the note with cues or notifications marking it as incomplete. Physicians returning to the computer could then complete their note. In a very busy environment many 'drafts' may be left on different charts. This solution should be no worse than is the case under paper charts if the CCIS facilitates the completion of documentation tasks.

Strengths and Limitations

The current study benefits from a clear, previously defined, definition of interruption [15], thus enabling comparisons to be made between our study and other units considering introducing a CCIS. We report interruptions occurring during one primary task, documentation, to investigate how well the CCIS fits in with the workload experiences of ICU physicians and nurses.

No studies, to our knowledge, have validated the WOMBAT method in ICUs, and this represents a potential minor weakness of this study. The results may not generalize to other wards, depending on the clinical information systems in place, particularly if those systems better tolerate interruptions to text entry. This study may have benefitted from collecting data from more junior physicians as they were more frequent users of the CCIS. We did not follow junior physicians as their varying familiarity with ICU work would present an obvious confounding variable. Future investigations of electronic documentation methods would clearly benefit from their inclusion in our study.

Conclusion

Currently, adoption rates of hospital based EMRs languish [20]. Challenges encountered by HCPs in ensuring informational continuity around their patients in the ICU environment may be either mitigated or aggravated by the tools they are provided. Clinical information systems designed for ICU environments may not take into account the interruption-rich environment. As HCPs become more familiar with the system, these effects may be lessened. Meanwhile, we posit that the lack of interruption tolerant data-entry mechanisms represents a deficiency that may impact documentation quality, communication between HCPs, and thus patient care.

Acknowledgements

We thank the staff and management of the PICU and GSICU, and observers Tineke Chattargoon, Sara Belton, Kelly Speer, Sally Ho, Deb Jandura, Aireen Wingert, and Ashwini Kulkarni. The authors acknowledge funding support from Alberta Health Services and Canadian Institutes of Health Research (CIHR). Abstract

Electronic nursing documentation constitutes technical, scientific, legal, and ethical documents. The objective of this study was to develop an electronic nursing documentation system. The system was developed in four phases (conceptualization, detailing, prototype building, implementation), and the knowledge base was based on domains and classes according to the NANDA-I, NIC, and NOC unified framework. The result is an electronic system (PROCEnf - USP - Nursing Process Electronic Documentation System of the University of São Paulo) which allows documenting nursing process generating reports of nursing process, besides supporting decisions on nursing diagnosis, expected outcomes, and interventions. Integration of different fields of knowledge, as well as the institutional feature of valuing continuous theoretical and practical improvement of nursing process were factors of success of this technological project.

Nursing informatics, Computerized medical records systems, Nursing diagnosis.

Introduction

The clinical nursing documentation has been oriented by the Nursing Process (NP). In Brazil, the NP was introduced in the 1970's by Wanda de Aguiar Horta to make nursing (which was conceived as the science that deals with human care treating the basic needs of the human being [1]) operational.

After using the NP in teaching and health services, it became known and recognized by the title of *Systematization of Nursing Assistance* (SAE). In this text, the expressions 'NP' and 'SNA' will be used with the same meaning, and describe a tool that provides a systematic guide to assist nurses develop a "a style of thinking that leads to appropriate clinical judgments" [2].

The NP orients a style of thinking in a continuum of questioning-answering-questioning in dynamic contexts for making appropriate decisions about what the patients' care needs are (diagnoses), what the expected outcomes are(outcomes), and what are the best nursing actions to meet the expected outcomes (interventions) [3].

Nursing documentation, in addition to providing technical, scientific, legal and ethical documents, and providing health institutions with important records for billing purposes, subsidizes the audit of nursing actions, and above all, allows estimating quality of care provided to the client [4].

However, one can observe that current nursing documentation often presents problems in terms of accuracy and relevance, and is rarely used to evaluate the care given.

The combination of three elements has been the focus to improve nursing documentation: definition of core data which should be included in each care meeting [5-6], internationally acknowledged as *Nursing Minimum Data Set* (NMDS), use of standardized language systems (or classification systems) [7-8], and networking [9].

Classification systems like *NANDA-International (NANDA- I* [10]*)*, *Nursing Interventions Classification (NIC)* [11] and *Nursing Outcomes Classification(NOC)* [12] are tools to improve reliability, validity and usability of nursing documentation.

In an attempt to integrate the classifications, NANDA-I, NIC, and NOC Alliance proposed a framework called NNN (NANDA, NIC NOC), which establishes a set of four domains and twenty eight classes to organize in a single framework the contents of NANDA-I [10], NIC [11], and NOC [12].

Using NNN framework in an electronic nursing system improves documentation, encourages nurses to adopt the NP, and improves diagnostic accuracy and patients' outcomes [13-14].

Computerized systems must overcome the mere transfer of documentation from paper to computer, and the "*check lists"* of diagnoses and nurses' orders emphasizing decision making

and nursing clinical judgment in patient care, expanding and supporting nurses' clinical decision

Decision Support Systems (DSS), which use databases (facts and/or rules), designed to assist a health professional in the process of clinical decision making have a great potential to help nurses cope with the required amount of data and information [15].

The Nursing Department (ND) of the University Hospital of the University of São Paulo (HU-USP), since its establishment, has implemented the NP in clinical practice. Aware of the advances in information technologies for health systems and the importance of ensuring that nursing was prepared for it, the ND included the computerization of clinical nursing documentation in its goals. Thus, since 2000 computerization of clinical nursing documentation was the main concern leading to the implementation of nursing classifications [16]. In 2003, by gathering researchers from the School of Nursing of the University of Sao Paulo, and nurses from the HU-USP, the project received a grant from the National Council for Scientific and Technological Development (CNPq), which enabled the leverage of the project to build a DSS for the nursing process and its documentation.

This paper reports the development of the system and its features.

Objective

To develop an electronic system for nursing documentation supporting adult clinical and medical patients' assessment documentation, and decision on nursing diagnoses, expected outcomes and interventions.

Method

This was a methodological research on technology production in the modality of case study. The system development method used 4 cyclical phases of technological product development: Conceptualization, Detailing, Prototyping and System implementation, adopting a project management model based on the *Project Management Institute* (PMI) [17].

The project presents a data model that enables electronic documentation of NP data of medical and surgical adult patients admitted in the HU-USP.

To develop the project, a multidisciplinary work group was established. The scope of the project was limited to NP documentation, in a way that it could be integrated into the hospital system of clinical documentation, .

The Steering Group of the system development was constituted by the Director of the ND, the Director of the Clinical Nursing Division of the HU; a nurse from the Nursing Continuing Education Service of the HU; two faculties of the School of Nursing of USP, and two staff nurses from Clinical and Surgical wards of HU-USP. In detailing phase for modeling data and system development, HU-USP contracted a company that had previously developed other systems for the Institution. Validation of use cases and system approval was done by Steering Group meetings with the technicians of the contractor company and a representative of the IT Department of the HU-USP.

Considering other areas within the ND will eventually incorporate the system, Directors and representatives of the Maternal-Child Nursing and External Patients Nursing Divisions were contacted, aiming at helping to organize materials the for databases.

It is noteworthy that nursing diagnosis classification was effectively in use in all the HU-USP wards since 2005 and that nurses developed tools to manually document nursing diagnoses, nurses orders and progress notes [18], which guided the construction of the electronic system.

The research project was approved by the Ethics and Research Committee of the Institution.

Results

PROCEnf-USP (Nursing Process Electronic Documentation System of the University of São Paulo) was developed in four planned phases.

The conceptualization phase emphasized the scope of the system, and established basic requirements. To do so, clinical and managerial Minimum Nursing Data was identified, and questionnaires were prepared to guide assessment data documentation needed for nursing diagnoses for clinical and surgical patients [17].

The framework for clinical assessment documentation was organized according to a database based on nursing diagnosis definitions and their components, following the hierarchy of domains, and classes proposed by the unified framework of NANDA-I, NIC and NOC [19], which could be a documentation guide able to generate a list of nursing diagnosis hypotheses in accordance with assessment data documented in the system.

Then, the automatic method used in the patient's nursing assessment record was to develop a "branched questionnaire" in which the nurse would go through several questions which could be customized for each patient [15].

The *PROCEnf-USP* guides the nurse to respond to a set of questionnaires with tabulated responses that lead to a set of likely diagnoses supporting the generation of diagnostic hypotheses. The evaluation, analysis, and choice of the defining characteristics, related factors and risk factors applicable in the structured database of likely diagnoses, allow the nurse to decide the set of diagnosis that best fits the patient's responses at admission, according to the nurse clinical reasoning, which corresponds to the phase of hypotheses testing, and final decision in the diagnostic process.

The branched questionnaire was developed by the Steering Group with questions based in the definitions, defining characteristics and related factors/risks of each diagnosis. For each class of unified framework of NANDA-I, NIC and NOC[19], questions were created on related subjects, whose answers include at least one cue for every diagnosis in the same class. In addition to the questionnaires for the 28 classes of the NNN structure, 4 other questionnaires which are required to admit any patient (social and demographic data, events which led to service, vital signs and conditions when arriving to be serviced) were created. The NMDS and the previously established institutional protocols guided the

definition of the additional content to the NNN structure. Once documented, the data of these 4 additional questionnaires which are relevant to any NNN class, are automatically copied to the class(es) in which they belong.

The linkages between answers and diagnoses were defined by consensus in the Nursing Group, based on the NANDA-I classification [10], the theoretical framework of reference areas, as well as on the clinical experience of nurses. In order to guarantee the linkages between answers and diagnoses in the logical system, every diagnosis had to have at least one answer they could be linked to. A rule was adopted that it was necessary that all diagnoses could be hypothesized at least once through the answers to questions included. Thus, after the nurse documents data collected (in total or in part), the system itself presents automatically the diagnostic hypotheses (calculated diagnoses). Then, the calculated diagnoses (hypotheses generated by the system) are confirmed or refused by the nurse, ensuring that final decision on the determination of the diagnosis is made by the user.

When relevant, questions with the same statement and same possible answers were repeated in more than one questionnaire (class), as recursive questions. These recursive questions, once documented in a class, are automatically documented in the other class(es) in which they are present. This avoids the duplication of work without violating the structure defined for the organization of questionnaires.

In order to support the choice of nursing outcomes and interventions, possible linkages between diagnoses and expected outcomes and between outcomes and interventions pertinent to the context of HU-USP were introduced in the system. Therefore, the components of the Nursing Classifications Advanced Node (NACEnf)[1] of the ND mapped 66 nursing diagnoses which are the most frequent in the Institution; for each one of these diagnoses, expected outcomes in the scope of HU-USP were chosen; for each outcome, interventions and activities pertinent to practices of the HU-USP were also chosen. Nursing diagnoses, outcomes and interventions were linked, therefore integrating NANDA-I [10], NOC [11] and NIC [12] classifications. Nursing diagnoses and expected outcomes were included in linkages according to their titles, and interventions were linked according to the activities recommended by the NIC. Linkages were based on available literature and reflections on clinical nursing practice in the Institution.

In the Detailing phase, software that would be used to develop the system was selected, as well as Use Cases, system interfaces and conceptual, logical and physical data modeling were described, adopting paradigms of ease of use and good quality user interface system. System specification documents followed current HU-USP standards, which use a sub-set of *Unified Modeling Language* - UML.

Information system project requires the use of databases characterized as structures of data storage and organization, arranged in a predetermined order according to system design, aiming at reorganizing data and producing certain information [20]. A database is usually maintained and accessed through software known as Database Management System (DBMS), which provides an interface (characterized as managing module) so clients can add, change or retrieve data.

In this project, the chosen database was Oracle®, because it is the tool used by HU-USP. This database provides an interface for customers to add, change, or retrieve data using a specific programming language: PL/SQL (*Procedural Language/ Structured Query Language*).

The data storage model used was relational, structured in the tables that allow for data relationship.

Platform.NET, a Microsoft® *framework* developed for internet, was used to establish the system web interface. F*ramework* is understood as a group of methods, standards and classes which define and offer resources for the development of systems.

The system has two environments: professional and academic. The professional environment will be used for documenting data of actual patients. The academic environment will enable the simulation of situations for teaching purposes with the same characteristics of actual clinical documentation, in which nurses, students and teachers register fictitious patients and simulate making diagnoses, selecting outcomes and interventions. The creation of fictitious patients prevents real patients from being included for education outside the field. This procedure is necessary to educate students and nurses and to keep the non-violation of ethical elements recommended.

When preparing the prototype, a preliminary version of the system was developed (functional prototype) aiming to verifying functions and business rules, and to observe system operation, facilitating the visualization of system constraints and system validation. During this phase, meetings were held to validate functions and business rules in the system.

During implementation phase, the system entered into a testing environment. Several versions were tested, and the system was finally approved by the Steering Group to enter into the production environment. In this phase, the system was installed on the HU-USP server, and *login* and access passwords were distributed to users.

PROCEnf – USP

The system allows the user, whether a nurse or a student, to make clinical decisions, supporting judgments to establish nursing diagnosis, expected outcomes and nursing interventions.

The user can choose between two paths, depending on their needs, being allowed to enter assessment data and view nursing diagnosis hypotheses generated by the system or to directly choose nursing diagnoses. Stages to be covered by the user follow clinical reasoning from documenting interview and physical examination data to documenting nurse orders.

To document data and care planning, the user shall follow *PROCEnf - USP* steps, detailed below:

1. Assessment**:** to begin documenting the assessment, it is necessary to choose an actual patient (in the professional environment) or a fictitious patient (in the academic environment).

[1]Nursing Classifications Advanced Node (NACEnf): Research support group created by the Nursing Department of the HU-USP aiming at deepening the application of standardized nursing language systems in the clinical practice of nurses.

2. Answer Questionnaire: the user shall answer the required Questionnaires and have the option of responding to the remaining Questionnaires (which are structured according to NNN classes) which it deems appropriate. Answers to Questionnaires generate Nursing Diagnoses hypotheses.
3. Calculate diagnosis: the system will show all diagnostic hypotheses on the screen, so the user can view Defining Characteristics, Related Factors, or Risk Factors that were identified through the answers documented in questionnaires.
4. Indicate diagnosis: the user can include Nursing Diagnoses in addition to the system hypotheses. On this screen, one has the option to look up Nursing Diagnoses definitions and add Defining Characteristics, Related Factors, or Risk Factors.
5. Select diagnosis: the user is responsible for choosing the most accurate diagnosis for the care of the patient.
6. Outcomes: after the decision on nursing diagnosis(es), the system will indicate the possible outcomes for each diagnosis, and the user will select one(s) that best represents the goals to for patient's care plan. The system allows adding other outcomes besides those automatically suggested.
7. Interventions: after the choice of Nursing Outcomes, the system will indicate the possible Interventions related to the Outcomes selected. The system allows the inclusion of other Interventions.
8. Activities**:** the system presents a set of nursing activities for each Intervention decided by the user. It allows the user to include other Activities that are linked or not to the Intervention selected. It is possible to add complementary information to an activity, such as "frequency" and "local application". The location of the patient's body related to the activity can be pointed out by the user by means of an iconographic system corresponding to the regions of the body.
9. Summary: the system displays a summary of the "Assessment" made by the user with the following data: evaluator's name, approver's name (certified nurses), questionnaires, diagnoses linked to their outcomes, interventions, and activities.
10. Reports: the user can request the following reports: "Assessment" (Nursing Diagnoses, Outcomes, and Interventions) "Daily Activities" (Nursing Diagnoses and Nurse Orders) and "Questionnaires".

Conclusion

The *PROCEnf-USP* will be registered as software by the USP Innovation Agency, and is ready to be implemented, evaluated, refined, and expanded.

Reasons because this technological production project was successful include institutional features (academic hospital, pro-active management of the ND; tradition in using nursing process; ND position in the organizational structure, for example), financial support, and positive attitudes toward collaborative work between clinical and research personnel from varied disciplines.

Abstract

Medication counseling is a central aspect of medication safety. Counseling refers to the process of informing, advising and administering medication to help patients manage their medication regimen. This pilot study examined 379 descriptions of medication counseling carried out in surgical care and documented in an electronic patient record system by using the Clinical Care Classification System. The objective was to identify counseling methods and to evaluate the need for additional counseling descriptor codes in the record. Eleven counseling methods were identified and the data were classified according to counseling methods with and without documentation of the nature of the interaction with patients. There were no descriptions of the nature of counseling conducted in 127 of the documented entries. These results can be used when developing the documentation of medication care in electronic patient records.

Keywords:

Medication administration, Patient safety, Counseling, Terminology

Introduction

The purpose of medication counseling is to support medication care by educating patients about their health status and medications needed to support it. This education during hospitalization results in the improvement of their knowledge regarding medications [1], increases their participation in care and enhances medication adherence [2].

Studies detailing the methods used in medication counseling are numerous. However, there is variability of study results based on methods used and outcomes measured in daily practice [1,3]. Standardized classifications can provide needed structure to organize the documentation and analysis of nursing care in a more systematic manner [4]. Structured descriptions of interventions used in an electronic patient record can be analyzed and evidence about safety, quality and use of resources evaluated [5, 6].

Most electronic systems that use structured data entry also allow supplemental information to be entered into the system in a narrative text format. Analyzing both the use of the structured codes and narrative text allows for the determination of potential additional structured codes that could further enhance the extraction and analysis of data [7]. In a study of narrative documentation in an otherwise structured clinical information system, Moss et al. found that almost 75% of the documented entries did not have a structured code in the system, increasing the time and effort needed to analysis these entries [7]. However, it has been shown that structured nursing terminologies, such as the Clinical Care Classification System, can be successfully used to classify nursing documentation in a structured format [8].

The purpose of this paper is to describe the evaluation of structured (using a nursing classification) and unstructured (supplemented free text) documentation of medication counseling in surgical care to determine methods used in counseling and how the narrative documentation in the record might inform additional coding for structured electronic documentation in the future.

Background

Finnish Classification of Nursing Interventions

The Finnish Classification of Nursing Interventions (FiCNI) has been implemented in electronic health record systems in Finland and is used in nursing care planning and documentation. Primarily, nurses use this portion of the electronic record, however all health professions can also access and document interventions carried out on patients. FiCNI is effectively a cultural revision of the Clinical Care Classification System (formerly the Home Health Care Classification) [9]. This standardized terminology consists of 19 care components, 164 main categories and 266 subcategories and is used to define planned and performed nursing actions. The *Medication component (G)* is divided into three main categories: *G.1 Medication Administration, G.2. Medication Side Effects and G.3 Medication Counseling*. In electronic health record systems documentation using intervention codes in these categories can be supplemented with free text narrative information. [9,10] According to a study focusing on the analysis of FiCNI use in nursing documentation in surgical and internal care the Medication component was one of the three most frequently used tools in documenting care provided [11]. In an other study assessing how the Medication component and its categories were used in daily documentation (N=4,594), 70 % of nursing actions

were found to be focused on medication administration and the single subcategory medication administration 'per os' was used most often [12].

Medication Counseling

Medication counseling is a central part of medication safety. Counseling refers to the process of informing, advising and administering medication to help patients in their medication regimen. [13] The objective of counseling is to promote its rational use to insure the best therapeutic action of the medication [1, 3]. Several studies show that lack of information causes patient non-adherence towards medication care regimen [1-3]. Kerzman and her associates (2005) found out that counseling was an important factor affecting correct knowledge about medication therapy at discharge. They also emphasize the importance of assessing a patient's cognitive abilities and highlight the provision of written material after counseling to reinforce the counseling success. [1]

In a previous study, five areas of teaching interventions related to medication management were found to be documented in the patient records in general medical ward: information, motivating conversations, explanations, instructions and setting expectations. According to the results documentation of patient teaching was inadequate. Although 80 % of patient records contained details of pedagogical relevance, they were not documented in a structured way and the use of terms and expressions were fragmented. [3]

The timing of counseling is extremely relevant for insuring correct knowledge regarding medication therapy. Counseling during hospitalization appears to help the patient better comprehend the information given and to ask for additional information. [1] Counseling is also needed when a medication care regimen changes. For instance new dosing and timing may cause adverse events in medication therapy if the new instructions are not given to and understood by patients. [1, 13-14]

Overall electronic information systems have been shown to reduce the number of medication errors associated with order entry [15-16]. Perhaps using standardized electronic documentation codes for medication counselling will help prompt caregivers to provide more complete and effective medication counselling to reduce errors and enhance therapeutic efficacy.

Purpose and aims

The purpose of this paper is to describe the evaluation of structured and unstructured documentation of medication counseling in surgical care to determine methods used in counseling and how they might be coded for structured electronic documentation.

Research questions in this study included:

- What are the methods used in medication counseling?
- How often is medication counseling provided to patients?
- Who provides medication counseling to patients?

Methods

De-identified patient data were extracted from the electronic patient records of a central hospital in Finland during 2004-2005. Before this analysis the FiCNI classification had been in use for two years in the electronic patient record system. The analysis was restricted to 11,543 patient records from a surgical ward in the year 2004. The Medication component as a code was used at least once in 3,902 (33.8%) of these records. For this pilot study the use of category *Medication counseling* of the FiCNI Medication component in the surgical ward documentation was analyzed. The code of medication counseling was used to describe nursing interventions in 379 records. These records included documentation entries of medication counselling in 269 patients, some of which had multiple admissions to the hospital that year.

Each record consisted of the following items: de-identified patient number, date and time of documentation entries, title of the personnel documenting, the heading and medication counseling category (G 3) with supplementing narrative text for each documentation entry. The data were extracted using SQL queries then converted to MS Access to process the raw data for research purposes. The data were analysed using MS Excel and further with SPSS 14.0 for Windows for descriptive statistics. Qualitative content analysis was used to analyse the content of narrative documentation. For the purpose of this study structured data was coded to the following variables: de-identified patient id (created for the study), counseling time by shift (morning/evening/night) and personal type (registered nurse/primary nurse/other).

Coding and analysis of the narrative documentation was performed independently by two researchers familiar with nursing practice and documentation. The disagreements (n=26) in coding were resolved by referring to the original free text descriptions. The content analysis of the unstructured narrative supplemental documentation revealed two main categories (Medication counseling with interaction and medication counseling without interaction) and further 11 sub categories that described the content of medication counseling (Table 1). The major category 'medication counseling with interaction' refers to documentation of medication counseling that involves interaction with the patient. For example, if the patient and nurse conducted a discussion of the proper method for self-administration of the medication, this documentation was categorized as 'medication counseling with interaction. On the other hand, if a nurse was only delivering information regarding a medication to the patient without any verification of the patient's understanding of this information, this documentation was categorized as 'medication counseling without interaction'. All documentation entries were entered into the information system by the healthcare providing the counseling shortly after the intervention was performed.

Results

Documentation Patterns

The data (N=379) evaluated consisted of descriptions of medication counseling entered in an electronic record in both structured and narrative formats. Medication counseling was

mostly provided by registered nurses (N=366). Only 13 other staff documented medication counseling in the record: primary nurses (n=10) and ward sisters (n=3). Counseling was documented only once for the vast majority of the patients (N=269), 74 patients had two documentation entries, of medication counseling 20 had three, 9 had four, 4 had five and 3 had six entries. Only one patient had seven narrative descriptions of counseling. Thus the average frequency for counseling documentation per patient was 1.4 per hospital admission. Counseling occurred mainly during the morning shift i.e. between 7 am and 3 pm (n= 283). Nearly 25% of the counseling (n=89) was provided in the evening before 9 pm, and 2% (n=7) during night shifts.

Unstructured Narrative Text Entries

In the category 'Medication counseling with interaction' the interactions with patients documented in the narrative text were mostly related to giving verbal instructions. Those counseling descriptions containing interaction could be differentiated into the categories: discussion (n=19), refresher/repetition (n=13) and side effects (n=9). Patient participation such as practicing was also used when educating patients to give injections for themselves. Those descriptions also contained assessment of the teaching success (e.g. *"injection succeeded").* When patients were given instructions verbally or given printed teaching material there usually were also narrative documentation regarding the patient's interaction with the nurse (n=30). For instance there were narrative documentation entries regarding changes in timing or dose or nutrition.

In the category Medication counseling without interaction the most often used method for counseling was giving verbal instructions when administering medication to patients (n=95) as shown in Table 1.

When administering medication verbal instructions contained descriptions regarding the dose, timing, route and the purpose of the medication. However, the descriptions of medication counseling did not contain any descriptions of the feedback from patients. Nurses documented using a variety of teaching materials with counseling leaflets being the most common. Many of these descriptions (n=47) did not have any information about patients reactions or comments.

Table 1- The contents of unstructured text and their frequencies complementing the use of FiCNI code Medication counseling (n=379)

Medication Counseling with Interaction	
Verbal instructions and written material	30
Practice and assessment	26
Verbal instructions - discussion	19
Verbal instructions - refresher	13
Verbal instructions - side effects	9
Demonstration and assessment (discussion)	1
Total	**98**
Medication Counseling Without Interaction	
Verbal instructions - medication administration	95
Written instructions: manuals, leaflets, other written material, video	47
Diary	6
Practice	5
Demonstration	1
Total	**154**
No narrative content	**127**

Discussion

Medication Counseling

The creation of categories to describe free text narrative entries analyzed in this pilot study were intended be very discrete to be able to differentiate the narrative descriptions of counseling methods. The categorization may have resulted in some overlapping between the categories *written instructions* and *verbal instructions with written material* due to some short narrative free text descriptions. The distribution of medication counseling with and without interaction as a result of the content analysis was a little surprising. However, based on the results it was obvious that a lot of teaching material is given to patients without any description of patient's learning outcomes in the records. The frequencies of documentation entries in the two categories counseling with interaction and counseling without interaction were eminent. They revealed that a lot of counseling is performed without any documentation of feedback from patients. We were unable to determine from the data whether the counseling occurred near discharge, an important time for counseling based on previous studies [1].

The most often used counseling method was discussion with patients i.e. giving verbal instructions when administering medication. However, medication administration should be interactive when possible and narrative entries related to counseling did not include any documentation of perceptions from patients. Friberg et al. (2006) in their study emphasizes the importance of the interaction between the patient and the nurse when delivering teaching material [3]. A variety of teaching materials such as manuals, leaflets and videos were also used when counseling patients. In this study the nurses had not documented any use of computerized or web-based material when counseling patients.

In this study, we found that the medication component was used for documentation of medication counseling in only 10% of the patient records in this surgical ward. It is not clear if this documentation is an accurate record of the frequency that medication counseling is actually occurring in this ward or if more counseling is occurring than is being documented. Counseling is a very demanding activity in hospitals due to the number of medications used in therapeutic treatment [13,15] and the amount of time needed to educate patients in their medication regimen [17]. Surprisingly, almost one third of the medication counseling documented did not have any narrative description. This may be due to an understanding among certain healthcare professionals as to standard and accepted content of medication counseling. Whether or not true the data does not support this argument. A better understanding of the reason for the lack of documentation would allow us to design either an educational intervention to encourage accurate documentation or an intervention to ensure that all patients are receiving medication counseling Previous studies suggest that medication education should be assessed to assure that patients receive appropriate medication education [3, 13]. Perhaps the addition of structured codes representing the content of counseling sessions would decrease the time necessary to document these actions and increase the rate in which nurses document counseling activities.

Additional FiCI Categories

According to previous studies nurses have a tendency to use the subcategories of the nursing classification in various ways. [12, 18] In this study nurses had also made narrative notes about medication care in *Activity* and *Health Behavior* components documentation section of the electronic record. Nurses also gave information to patients concerning side effects of medication therapy using the medication counseling code. In the FiCNi classification the medication component has a structured code for side effects. Thus, these descriptions should be additional information to documentation using the side effect code.

The data for this pilot study were collected only from one surgical ward. Thus, the results only reflect the situation in one hospital ward. However, the data provided a good opportunity to analyze counseling methods used by nurses. The use of a nursing classification in this electronic medical record is also available for physicians. These data only represent nursing staff using the platform for documenting medication counseling. Pharmacists being an important group regarding knowledge in medication therapy did not participate in this hospital in the medication administration process. Increasing the use of this portion of the record for documentation of medication counseling by other healthcare professionals would increase our ability to monitor this interventions and its impact of patient care.

More data is needed to make accurate recommendations for potential additions to FiCNI codes for medication counseling. However, it seems that those counseling methods containing interaction with patients: verbal instructions with discussion, refresher, and use of written material could be potential additional codes in the future. The most natural and beneficial time for counseling might be when administering medication to patients. Increasing the use of and documentation of medication counseling with patient interaction could increase medication safety and patient satisfaction. For example, patients need practice and nursing feedback to adequately learn to give themselves injections. This could happen after a nurse's demonstration during the medication administration process. The option for patients to keep a diary and get feedback from the healthcare provider is another potential addition to structured codes that might be added to the category of medication counseling in the future.

Conclusion

The narrative free text analyzed in this study suggested the need for additional structured codes be added to the FiCNi component for medication counseling. The structured coded subcategories would help nurses document more precisely the content of nursing activities in medication care. More research is needed to test the validity of the subcategories prior to implementing them as a part of medication component and medication counseling category of the FiCNI.

Abstract

Anatomic pathology reports (APR) provide diagnostic and prognostic information crucial to patient care, clinical research and epidemiology. Currently, it is difficult to collect and exchange APR data between different healthcare organizations at an international level. Objective: IHE and HL7 anatomic pathology joint efforts aim at providing a methodology and tools to define an international HL7 "Clinical Document Architecture" (CDA) implementation guide for APRs and especially in the domain of cancer. Methods: A four-step methodology is employed, consisting of comparing existing clinical model of APRs originating from different countries; deriving consensus-based clinical models (Delphi technique); providing the corresponding HL7 CDA implementation guide ("CDA templates") and validating these templates. Results: International experts defined HL7 CDA implementation guides for breast and colon cancer APRs within an IHE content profile. CDA templates include required data elements, as well as optional ones, that can be further specified as required in national extensions. Conclusion: This study demonstrates that it is possible to define an international HL7 CDA implementation guide for cancer APRs. Further efforts are needed to provide CDA templates for approximately 60 other cancer APRs dedicated to different organs, diagnoses, and procedures as well as for APRs of non neoplastic pathologies. The methodology is not confined to APRs and could be applied to clinical documents of any type.

Keywords:

Anatomic pathology reports, Synoptic reports, Cancer checklists, Structured reports, Structured data entry, Delphi method, IHE, HL7, CDA.

Introduction

Anatomic pathology reports (APR) document the pathologic findings in specimens removed from patients for diagnostic or therapeutic reasons. This information can be used for patient care, clinical research and epidemiology. Currently, APRs for cancer patients have generated the greatest need for the collection and exchange of data contained in APRs, and many organizations have created templates in an effort to standardize APR reporting. The heterogeneity of such templates and lack of standards for structuring the relevant data elements in reports, hamper the exchange of this information among different information systems and healthcare organizations. Standardizing and computerizing APRs is necessary to improve the quality of reporting and the exchange of APR information[1].

As part of joint IHE and HL7 anatomic pathology activities, our objective is to provide a methodology and tools that facilitate the development of international clinical models for APR, including cancer APRs, as well as the production of the corresponding HL7 CDA implementation guides (CDA templates).

Several studies provide recommendations that delineate the required, preferred, and optional elements which should be included in any APR, regardless of report types (e.g reporting guidelines in[2].

Several international initiatives intend to define standard clinical models for specific types of APRs. For example, in the cancer domain, in the United States, the CAP (College of American Pathologists) has published 67 cancer checklists and background information[3]. In France, the SFP (French society of pathology) has published 23 minimum data sets for 21 cancer locations[4]. Together, the recommendations for generic and specific APR reporting have become clinical guidelines, the use of which may be required by accrediting bodies. The majority of encoded elements of these clinical models are associated with encoded value sets. The most frequently used coding systems in anatomic pathology domain are SNOMED Clinical Terms®, ICD-O-3 and ADICAP in France [5].

Since these standardization efforts are conducted at a national level there are some discrepancies between clinical models across countries and even some heterogeneity between clinical models within the same national initiative. There is a need to propose a methodology and tools to achieve better consistency of clinical models at an international level. There are several methods to achieve consensus-based agreement among experts. One such method is based on Delphi technique: a sys-

tematic, interactive forecasting method that relies on a panel of independent experts[6].

In addition to standardizing the cancer APR contents, it is necessary to computerize them. Several studies have focused on defining an appropriate IT standard comprising the structured and encoded clinical documents (e.g. CAP eCC). HL7 CDA is one of the most reliable standards that can support these needs[7]. CDA allows the clinical data to be both human and machine-readable and provides a framework for incremental growth in the granularity of structured, codes-bound clinical information. However, there are currently very few national initiatives of CDA implementation guides for the APR, one example being developed at the National IT Institute for Healthcare in the Netherlands, another one by HL7 Germany[8].

Materials and Methods

We followed a 4-steps methodology to define an HL7 CDA implementation guide for APR:

Step 1: Defining clinical models for APR (structuring and standardizing APRs medical content)

Clinical models for APR should address all Anatomic Pathology reporting domains such as surgical pathology, cytology, autopsy and even research (e.g. molecular biology or tissue micro arrays (TMA)). In order to ensure consistency among clinical models, we first defined a set of constraints that apply across all APRs regardless of domain. We then further identified the set of constraints that apply across all **cancer** APRs.

Generic clinical model for APR

Based on analysis the available recommendations that outline elements which should be included in an APR regardless of report types [2], we identified the sections of the generic clinical model for APR.

Generic clinical model for cancer APR

Based on the recommendations[2], specific to cancer APR, we defined sub-sections specific to the generic clinical model for cancer APR [2]. Then, based on comparison of the existing organ/diagnosis/procedure specific cancer checklists as defined by the CAP and by the SFP, we identified the elements that were most frequently present in the various organ/procedure specific checklists.

Organ/diagnosis/procedure specific clinical models for cancer APR

Based on the generic clinical model for cancer APR, we created organ/diagnosis/procedure specific clinical models. We merged the CAP and SFP checklists keeping a single occurrence of each common data element, and flagged the other elements with the name of the source template.

Step 2: Validating clinical models for APRs

Consensus sessions were organized by IHE and HL7 Anatomic Pathology workgroups and European COST action IC0604 in order to validate the clinical models for cancer APRs. A panel of experts first agreed on the sections of the generic clinical model for cancer APR during two face-to-face meetings. In France, two online questionnaires were published in order to evaluate discrepancies between CAP and SFP cancer checklists for breast cancer and colon.

According to the Delphi method, after the first survey round, a facilitator provides an anonymous summary of the experts' responses with their comments, in order to decrease the range of answers in the second round. After achieving the consensus or stability of results the mean or median scores of the final rounds determine the results.

Step 3: HL7 CDA implementation guide for APRs

HL7 CDA Release 2.0 provides a general architecture for designing and implementing clinical documents in an electronic format that is both human and machine-readable. Because of the architectural nature of the CDA standard, individual implementations are always associated with an implementation guide (also called "HL7 CDA template"), i.e. a document that describes how the CDA standard should be implemented for a particular type of document used in a specific context. A CDA document begins with a header that states the context of care in which the document was produced, identifies the various participants involved (patient, care providers, devices, etc) and states the responsibilities regarding the content of the document. The body of the document can be organized as a hierarchy of sections. Each section lays out its text for the reader, and may in addition carry fine-grained coded machine-readable data, corresponding to that text. We mapped the various roles of professionals involved in an APR to header elements. We then defined body sections, and assigned each section a unique code, a title and a text block. Finally, we coded the fine-grained machine-readable data into entries attached to the sections. Codes have been assigned to sections and to the various entry elements (acts (observations, procedures, etc), entities (specimen)) carried within the entries.

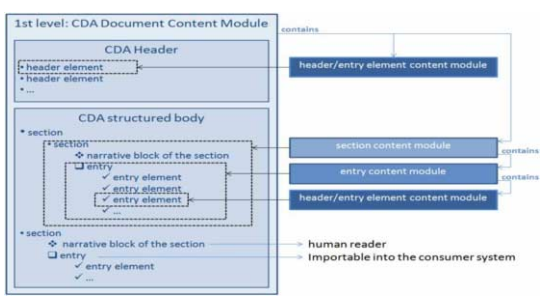

Figure 1- Hierarchical organization of CDA R2 content modules

Vocabulary domains provide value sets for coded CDA components. Some of these vocabulary domains are internally defined by HL7 V3. Others are drawn from external coding systems such as LOINC or SNOMED CT. Whether internal or external, every vocabulary domain has a unique HL7-assigned identifier (HL7 OID which is an ISO object identifier), and every concept within a vocabulary domain has a unique code and an associated display name in a given language. For some of the CDA components, the vocabulary domain is imposed by the standard. For others, the implementer is free to choose

from any relevant external source, such as LOINC, SNOMED CT or some other realm-specific vocabulary. For example, the possible values for the observation "histological type" in CAP cancer checklists are encoded using SNOMED CT values sets, while in France, SFP cancer checklists these values are encoded using ADICAP or ICD-O-3 values sets.

All the operations described above have been eased by the reuse whenever possible of relevant templates for CDA elements that had formerly been defined by the Patient Care Coordination (PCC) and Laboratory (LAB) domains of IHE.

Step 4: Evaluating HL7 CDA implementation guides

The good practice in building HL7 CDA implementation guides is driven by this key principle of the standard – "*one single xml schema CDA.xsd for all types of clinical documents*" – Therefore, like all other CDA implementation guides, this APR CDA implementation guide relies on the original CDA.xsd schema, unchanged. The set of templates that compose the implementation guide express constraints restraining the options allowed by the original CDA.xsd schema, and binding its coded elements to predefined value sets.

These constraints are expressed in formal language within the implementation guide, and will also be translated as assertions into a schematron file[9]

From that point, the process of evaluation of the implementation guide will consist in three steps:

a) Build a collection of APR instances conforming to the implementation guide, with a clinically relevant content provided by the domain experts (pathologists and clinicians).

b) Validate each APR instance against the standard CDA.xsd schema.

c) Validate each APR instance against the templates, applying the schematron file of assertions expressing the constraints of these templates.

Results

Clinical model for Anatomic Pathology Report (APR)

The generic clinical model for APR is structured into six sections; three required sections (Clinical Information, Macroscopic Observation and Final Diagnosis section), one conditional section (Intra-operative Observation) and two optional sections (Microscopic Observation, Tissue Dissection and Ancillary Tests). We defined additional constraints for the generic clinical model for cancer APR.

Table 1 summarizes the six sections and the corresponding sub-sections and entries of the generic clinical model for cancer APR (entries specific to cancer as designated by the * symbol).

In addition, two clinical models for organ-procedure specific cancer APRs (breast and colon) constraining the generic cancer model were defined. Following the consensus sessions conducted in France, SFP cancer checklists were aligned to the corresponding CAP cancer checklists in order to be defined as French national extensions of these CAP checklists.

Table 1- Sections, subsections and entries of the generic clinical model for cancer APR.

Generic cancer APR sections	Generic cancer APR sub-sections/entries
CLINICAL INFORMATION Clinical information provided by the ordering physician: reason for anatomic pathology procedure, active problems (preoperative and/or postoperative diagnosis, lab data), collection procedure(s) and specimen description(s) for all delivered specimen(s) reported separately.	**Reason for AP procedure** **History of present illness** **Active Problems** **Specimen clinical information entry** • Specimen Information Organizer o Collection procedure o Specimen(s) type o Specimen location
INTRAOPERATIVE EXAMINATION (conditional) Intraoperative diagnoses +/- images for all delivered specimen(s) reported separately.	**Intraoperative entry** • Specimen Information Organizer o Diagnostic observation o Link(s) to images
MACROSCOPIC OBSERVATION Collection procedure(s) and specimen description(s) (if not provided by the ordering physician), +/- gross findings +/- images for all delivered specimen(s) reported separately.	**Macroscopic observation entry** • Specimen Information Organizer(s) o Collection procedure o Specimen type o Diagnostic observation(s) o Link(s) to images
MICROSCOPIC EXAMINATION (Optional) Histopathologic findings (e.g results of histo-chemical and immunohistochemical stains) +/- images for some delivered specimen(s) reported separately.	**Microscopic observation entry** • Specimen Information Organizer(s) o Diagnostic observation (s) o Link(s) to images
DIAGNOSTIC FINDINGS Diagnoses +/- additional pathologic finding(s) +/- results of ancillary studi(es) (=cancer checklist(s), in case of cancer) +/- images for all specimens delivered, reported separately.	**Diagnostic findings entry** • Specimen Information Organizer(s) o Tumor location* o Tumor histologic type and grade* o Tumor extension (including pT, pN)* o Treatment effect o Additional findings o Results of ancillary techniques o Link(s) to images
TISSUE DISSECTION AND ANCILLARY TESTS (Optional) Tissue dissection (representative specimens and derived specimens dissected for other ancillary procedures (flow cytometry, cytogenetics, molecular studies, electron microscopy, etc) or biorepository) for all specimens delivered, reported separately.	**Tissue dissection and ancillary tests entry** • Specimen Information Organizer(s) o Dissection technique o Specimen type o Ancillary technique

HL7 CDA implementation guide for APR

HL7 CDA implementation guide for APRs consists in a set of CDA templates described within the IHE Anatomic Pathology content profile "Anatomic Pathology Structured Report" available on the IHE web site[10].

With regards to the header, we have defined the content modules representing the various participants involved in the documented act, and/or in the production or stewardship of the APR.

With regards to the body, we first defined CDA templates for the six sections (Clinical Information, Intra-operative Observation, Macroscopic Observation, Microscopic Observation, Final Diagnosis section, Tissue Dissection and Ancillary Tests). Each section (e.g "Clinical information") is provided with a unique code, a title, a free text zone, the description of sub-sections (e.g "Reason for anatomic pathology procedure") and entries (e.g "Specimen Clinical Information") as shown in Figure 2.

We then defined CDA templates for entries. Each entry (e.g "Specimen Clinical Information") contains a unique code and the description of the embedded entries or entry elements (e.g "specimen collection procedure", "effectiveTime" or "targetSiteCode"). One or more organizer may be used according to the number of specimens to which information is attached to. Each organizer allows identifying one specimen and describing its related acts (observation, procedure…).

Figure 2- CDA template of the section "Clinical Information"

With regards to the encoding process, in order to maintain different value sets derived from different coding systems, we have used the capacity of HL7 CDA to express any encoded element as two or more equivalent codes derived from different vocabularies (coding systems).

HL7 CDA implementation guide evaluation

A collection of APR instances of cancer APRs, including breast and colon cancer APRs, was built conforming to the implementation guide and validated against the standard CDA.xsd schema.

Discussion

Based on different initiatives for standardizing Anatomic Pathology structured Reports (APR) and as part of joint IHE and HL7 Anatomic Pathology activities, international experts defined an HL7 CDA implementation guide for structured Anatomic Pathology reports and in particular cancer structured reports. In order to ensure consistency, the organ specific HL7 CDA templates are based on a common generic template, including the constraints that apply across all APR regardless of the reporting activity, procedure, diagnosis or organ. Subsequent templates would aim to maximize the reuse of the data elements across templates whenever possible.

HL7 CDA templates support semantic interoperability of clinical data that are both human readable and machine-processable and that can be stored in databases to be further queried or mined. Furthermore, filtering algorithms may be applied on machine-processable data elements of HL7 CDA templates in order to exploit different clinical information according to different contexts of use (patient care or research).

Medical consensus is not easy to achieve at regional, national, and international levels on important features that should be reported, as well as the vocabulary or coding system to use. Although there were many similarities between, for example, the CAP and SFP cancer checklists for breast and colorectal cancer, it was impossible to achieve exact mapping between them. We found discrepancies in comparing value sets of encoded elements. Furthermore, common data elements may be encoded using different reference terminologies (e.g some data elements are encoded by CAP using SNOMED CT, while they are encoded using ADICAP or ICD-O-3 by SFP in France).

More generally speaking, due to frequent changes in the value sets, the use of ISO/IEC 11179 (Information Technology -

Metadata registries) has been proposed to allow report senders to reference externally accessible metadata dictionaries for each data element. Given the current development of various vocabulary server projects (such as the Distributed Annotation System (DAS) Server[11], LexGrid [12] and Common Terminology Services (CTS2); an additional attribute specifying the communication method with the referenced server would be necessary.

Given this issue of value set variability across countries and over time, it may be necessary to provide access to the entire current available value set for each data element. Ideally, the upcoming versions of the CDA standard would provide an attribute for directly referencing an externally accessible local (or a global) vocabulary server for each coded data element, thereby allowing the recipient of the report to query the sender's vocabulary server for a data element description and a value set belonging to the unique id of the given data element. Additionally, standardized methods for capturing form rules governing dynamic data element availability and values within the current template instance (for example using XForms) would need to be investigated and agreed upon by experts for each template, allowing for consistency across various laboratory information systems. The most appropriate method to ensure the intended layout and appearance of the transmitted report remains to be identified.

This study demonstrated that it is possible to define international IHE content profiles for both a generic cancer APR and organ/procedure specific cancer APR and to derive from these HL7 CDA international implementation guides, national extensions taking into consideration national or local constraints (e.g. local coding systems).

With regards to the evaluation step, our perspective is to make a broader use of schematrons. This rule-based validation language for making assertions about the presence or absence of patterns in XML trees is currently used to validate each APR instance only against the CDA schema. We plan to validate instances against specific APR templates, applying the schematron file of assertions expressing the constraints of these templates. Furthermore, the successful tests of the content profile at IHE Connectathons could attest the quality of the CDA templates. At last, only their adoption in real world implementation will attest their relevancy.

Further efforts are needed to provide implementation guides for the remaining organ-specific cancer APRs and also for APRs of non-neoplastic pathologies.

It is necessary to develop a tool that automates and supports the modeling process in order to cover all cancer domains in an acceptable period of time.

One of the crucial issues is not only to guarantee the consistency between APR templates at an international level but also to ensure their consistency with other clinical domains such as IHE Laboratory or Patient Care Coordination. The on-going international effort aimed at providing world-wide template repositories will allow the reuse of previously defined templates in order to avoid duplication of data elements across domains and to save time and effort[13].

The modeling methodology in its three phases of consensus achievement, modeling, and evaluation could be applied not only to the other organ/procedure specific APRs, but also to clinical documents of any type. The topic has now emerged as an important area of standards development, and a useful focus for international cooperation[14].

Peri-operative Communication Patterns and Media Usage — Implications for Systems Design

Ero S. Karlsen and Pieter Jelle Toussaint

Department of Computer and Information Science, Norwegian University of Science and Technology, Trondheim, Norway

Abstract

Inter-hospital communication amounts for a great deal of clinicians' work time. While communication is essential to coordinate care, it can also be time consuming and interruptive, and breakdown in communication is an important source of medical errors. One contributor to the interruptive nature of communication is the use of synchronous media, and there is clearly a potential for novel technologies. To assess communication patterns and media usage we performed an ethnographic field study in the peri-operative environment at a Norwegian hospital, as well as interviews with nurses. We analyze the results with regards to choice of media, characteristics of the conversations taking place and meta-messages, and account for addressing, obtrusiveness and information richness in the message exchanges. We find a relative high degree of interruptiveness in communication, and ascribe it to 1) a lack of situational awareness between locations in the peri-operative domain, as well as 2) use of synchronous media. This suggests that design of novel technology for intra-hospital communication should aim at supporting sender-receiver awareness and signaling of availability.

Communication, Hospital communication systems, Qualitative research

Introduction

The amount of time spent communicating in health care is vast and still expanding [1, 2]. While communication is essential to coordinate care, it can also be time consuming and interruptive [3, 2], and breakdown in communication is an important cause of medical errors [4]. Contributing to the interruptive nature of the communication are the use of synchronous media, such as telephone and pager, and the lack of situational awareness (i.e. sender is not aware of where the receiver is or what she is doing).

For the purpose of this paper we broadly divide intra-hospital communication into two main categories: 1) clinical problem solving, and 2) coordination. (Of course, the communication serves several other more social and play related purposes, less directly work related but not necessarily less important.)

We use clinical problem solving to denote communication regarding diagnoses and treatment plans. Aimed at problem solving and decision making, this form of communication often go on for an extended period of time, and is sometimes iterative in nature (i.e. diagnoses can be changed, new treatments tested). While less rigid, this process is similar to scientific inquiry, and communicative challenges are related to sharing of complex information, documenting the clinical reasoning process, negotiating and supporting organizational memory [5].

While clinical problem solving is a ubiquitous process, which might occur anytime (it is not uncommon, for instance, that surgeries reveal physical findings which prompt new diagnoses), given the scope of this study we are more concerned with communication related to coordination. This form of communication is usually more immediate, and the need for support of organizational memory, documentation and storing of information is less pronounced. However, coordination-related communication brings its own set of challenges: due timing of messages; level of obtrusiveness; and sender-receiver awareness and feedback.

Our study is concerned with the communication patterns in the so-called peri-operative domain. Peri-operative refers to three phases: pre-operative, intra-operative, and post-operative. It starts when a decision is made to operate on the patient, and terminates with the resolution of the surgical sequelae [6]. Through a qualitative analysis, we aim to characterize the communication patterns in the peri-operative domain, and to identify areas where novel communication technologies can play a role, as well as central requirements for design of such technologies.

Background and framework

Coordination and articulation work

Coordination can be viewed as the problem of managing interdependencies between activities performed to achieve a goal [7]. The resulting joint activities are in a sense "created from the goal backwards" [8].

For each actor to be able to plan and perform his actions optimally he needs to know his team members' goals and actions. In aviation the concept of *situational awareness* has been used

to analyze accidents and improve safety, and in later years the concept has been adapted in health care. Simply put, situational awareness is the shared understanding of what is going on now, as well as what is going to happen next [9]—a prerequisite for successful coordination. To achieve an acceptable level of situational awareness each actor must ensure that his actions and plans are shared with other members of the team, and he must ensure that he himself obtains relevant information about the plans of others. This *articulation work* [10] increases when the cooperative work lacks a well-defined point of control, which is usually the case in hospital work, where the participants must themselves ensure that their combined efforts result in the desired outcome. Each participant's actions must be articulated, communicated and negotiated with the other participants (*ibid.*). Managing the distributed nature of cooperative work, in short, takes a lot of work.

Media use and communicative strategies

The nature of health work necessitates complex communication, using different media. Often the communication is characterized by a high degree of cognitive complexity, and the communicative process itself might represent several challenges (time constraints, changes during the conversation, dependency on feedback). Te'eni [11] presents several proposals about communicative strategies and choice of media in different situations. Harr and Kaptelini [12] provide an analytical tool for analyzing interruptions in social contexts and show how interruptions often spread in organizations with a ripple effect.

Communication as social action

In addition to the obvious practical reasons for intra-hospital communication, any use of language also acts on a social level. This dimension also impacts the more instrumental uses of language and needs to be accounted for, for instance with regards to choice of media, i.e. how much bandwidth a media has for this contextual information.

Conversation analysis and interactional sociolinguistics perceive language as socially structured, with set patterns, independent of the linguistic content. Pauses, overlappings, tone of voice, and gestures—meta-messages—are seen as highly relevant aspects of a conversation which must be considered in addition to the pure linguistic exchange [13].

Analytical framework

Reflecting a hierarchy of granularity, we distinguish between three types of communicative acts.

- Conversations
- Messages
- Meta-messages and cues

Our framework draws from discourse analysis, which itself encompasses a variety of analytical approaches (*ibid.*). While our definitions of conversation and message might overlap with existing concepts, they are here defined in a way we deemed useful for the analysis of this particular domain. Our definition of meta-messages is congruent with its use in pragmatics [14].

Conversations constitute the macro level, the on-going message exchange that takes place in intra-hospital coordination and medical problem solving. In principle, a conversation could span anything from seconds to years, but in our case we focus on the more immediate conversations with a shorter time span.

Messages are the building blocks of the conversation and are associated with some media used for exchange (i.e. telephone, face-to-face encounters, email). Messages are exchanged in a typical turn-taking fashion, where sender and receiver alternate between interpreting and constructing messages.

Meta-messages and cues (ibid.) are any contextual information that adds meaning to the messages and conversation. Meta-messages can be purely linguistic (i.e. an ironic email), or they can be extra-linguistic and conveyed through tone of voice, gestures, facial expressions, etc.

In addition we have identified three aspects of particular interest in message exchange in health care:

- *Addressing.* Strategies used to find and deliver the message to the right person, group or role.
- *Obtrusiveness.* The degree to which the sending of a message interrupts the receiver.
- *Information richness.* The degree of contextual information associated with a message. Ideally, the message should convey enough information to enable the receiver to interpret it without having the spend time asking for clarification or consulting other sources, but not so much information that the receiver have to filter out superfluous information.

Materials and methods

Study design and setting

We conducted a non-participatory qualitative observational study at a Norwegian University hospital in the winter of 2009. Three observations were performed over different days, for 16 hours taken together. Two of the observations were performed in the operating theatre, while one was conducted as a shadowing of the patient in the peri-operative environment. This involved following the patient from preparations done in the ward, through to surgery and admission to the recovery.

The observations were based on ethnographic methods adjusted for requirements engineering for IT systems—so called *rapid ethnography* [15]. This involves more structured and focused observations than in traditional ethnography (*ibid.*). Data from the observations were recorded using free text notes. In addition to the observations we performed two semi-structured interviews with operating nurses, which each lasted about half an hour.

The observations were performed by one of the authors. To ensure a correct understanding, the clinicians were inquired for clarifications when appropriate during the observations. We also presented some of our preliminary interpretations during the interviews to ensure their validity.

Ethical considerations

The study design was approved by the Norwegian Regional Committees for Medical and Health Research Ethics, and the Norwegian Social Science Data Services. To protect the participants in the study, the data was de-identified and stored securely. Informed consent was collected from the participants.

Results

The peri-operative domain

Our observations are limited to the different procedures during the day of an operation—i.e. they do not necessarily cover the full length of the pre- and post-operative phases, which might extend outside the realms of the hospital and for a period longer than a day. The pre-operative phase corresponds to preparations done to the patient at the ward (typically physical examinations, confirming that the patient has not eaten, and premedication for anesthesia). The inter-operative phase starts when the patient is moved to the operating room, and the post-operative phase starts when the patient is moved to the recovery ward.

As we see, the phases have spatial boundaries that involve moving the patient to different locations in the hospital. At the hospital where we conducted our observations, the wards, the operating room and the recovery ward were located in separate places in the building and on different floors. This contributed to reducing the spatial awareness of the peri-operative process as a whole, as well as to the use of communication media like telephone and intercom to facilitate coordination.

Typically, an operation would have its immediate center of control in the operating room. Surgeries were scheduled with date and time, so each of the three locations corresponding to an operative phase (ward, operating room, and recovery ward, respectively) would have an idea of what would take place when, and this facilitated what we might call implicit coordination.

The transition between the operative phases still had explicit markers. Staff at the operating room would notify the ward when it was time to pre-medicate the patient, and when the surgery was about to end the staff would likewise notify the recovery ward that the patient would soon arrive. The phases were further distinguished by handovers between the different locations: Before surgery, staff from the ward transported the patient to the operating ward; after surgery, staff from the operating theatre transported the patient to the recovery ward.

Conversations, messages and meta-messages

Conversations in the peri-operative domain were predominantly concerned with coordination. Communication regarding medical problem solving did still occur, though, in one of two ways: 1) Either as informal information exchange between clinicians regarding patients they were responsible for, as when one operating surgeon inquired the assisting surgeon about the condition of a patient who had been operated the previous day, or 2) arising as a consequence of an unexpected medical event. During one of the surgeries a bile leak occurred, prompting the clinicians to engage in conversations regarding the cause, as well as conversations coordinative in nature to correct the condition.

In general though, the conversations were of a coordinative nature, with content of limited complexity, and of short duration. Often conversations consisted of no more than notifications or prompts—one message and its acknowledgement, as when one of the operating nurses called the ward to ask them to pre-medicate the patient. The level of meta-messages was in these cases restricted by the medium—telephone or intercom—leaving only the speech pattern and tone of voice to convey emotions.

Not surprisingly, the use of meta-messages was much more pronounced in the face-to-face communication, which took place inside the operating theatre. In this setting, the coordination was highly dependent on non-verbal cues, such as what personnel was in the room, where equipment was placed, etc. Many actions were carried out without being explicitly called for. In one instance, the surgeon entered the operating room and was dressed in his operating coat by a nurse before both of them proceeded to prepare equipment—without a word having been exchanged. The verbal communication had been replaced by a set of subtle cues related to their position in the room, bodily gestures and placement of objects.

Another occasion illustrates the importance of meta-messages in addition to verbal communication. When a piece of equipment broke down, a discussion between one of the nurses and one of the surgeons arose regarding the cause. Their opinions differed, and the nurse—while not willing to give in—softened the potential aggressiveness in her insistence using several meta-messages, such as self-directed irony and smiling (in all probability also reflecting the authority gradient between nurses and surgeons).

Addressing, obtrusiveness, and information richness

Communication between the different locations in the hospital was in general characterized by unspecific and what we shall call relayed addressing. In the pre-operative phase, personnel in the operating room usually communicated with the ward where the patient resided using telephone. This involved calling the coordinating nurse at the ward, whereupon he would relay the message to the personnel concerned. By assigning a nurse to the role of coordinator other staff members were alleviated from some articulation work, but a more direct addressing scheme would be technologically feasible and could free up personnel for more direct medical work.

Incoming messages to personnel in the operating room usually came through the intercom, broadcasting the message to all personnel in the room, while the anesthesia nurse usually was the one to reply since he was the one nearest to the intercom.

Lack of information richness was to a little degree perceived as a problem in this particular domain, which should not come as too big of a surprise given the relatively straightforward and simple messages exchanged. In conversations dealing with medical problem solving, adequate information richness in

messaging would be a more important requirement.

Our general impression was that the tolerance for obtrusive communication was high. Not uncommonly, the receiver of a message was interrupted in her work and had to use time to reengage in it. The media mostly used for communication—telephone and intercom—added to the problem of interruptions. Given the synchronous nature of these media, they are often convenient for the sender, who gets immediate feedback on her request—but correspondingly interruptive for the receiver.

The interviews with nurses confirmed the problems resulting from situational awareness. A common complaint was that they lacked an awareness of what was going on in other locations, and that agreements about handovers could lead to waiting and delays.

The lack of team situational awareness between sender and receiver in a conversation also added to the problem when using synchronous media. For instance, when telephoning there is no way for the sender to know whether she will interrupt the receiver. In some cases messages were delivered personally, in the sense that personnel entered the operating theatre to engage in conversations with the surgeons. While in one sense obviously intrusive, these occasions enabled the surgeons to signal their degree of availability, and this awareness enabled sender and receiver to negotiate and adjust the form of communication literally on the spot. Even though the degree of interruptions was high, this seemed to be integrated in the work routine and a taken for given.

Discussion

As our observations were restricted to the peri-operative environment, they cannot be generalized to intra-hospital communication as such. Still, there is reason to believe the coordination problems of the peri-operative domain, and the message exchanges it prompts, are common also in other areas of the hospital. The peri-operative domain represents a scarcity of resources (rooms, equipment, and personnel), and work must be prioritized and coordinated so as best to utilize the resources available. This is similar to the situation in other domains in the hospital, like the emergency room or when using equipment and personnel for diagnosing (for instance X-ray examinations). However, the peri-operative domain is less representative of the medical problem solving communication, which is characterized by more complex conversations over longer periods of time.

To summarize our main findings:

- Physical dislocation results in lack of situational awareness in the peri-operative phase.
- The lack of situational awareness contributes to interruptions, since there is a lack of sender receiver awareness in message exchange.
- Addressing is often unspecific and relayed through several instances.
- Use of synchronous (i.e. interruptive) media is convenient for the sender, but often interrupts the receiver.
- The interruptive nature of communication seems to be accepted and integrated in the work process.

Reflecting on these findings, we think there is a potential for improving communication in the peri-operative (and similar) domains through use of novel communication technology. Problems regarding addressing and interruptions to a large degree stems from a lack of situational awareness. This could be alleviated either by enhancing awareness through changing procedures or the physical space, or by integrating a larger degree of sender-receiver awareness in communication technologies. Also, we believe that more asynchronous communication means could potentially be utilized to reduce interruptions. This is in accordance with earlier findings and recommendations [16- 18]. Again, a larger degree of sender-receiver awareness could potentially provide some of the current benefits of synchronous media also in asynchronous media. Lastly, one should keep in mind the importance of meta-messages in conversation, and we would caution against replacing information rich media or face-to-face communication with technologies that do not support the same bandwidth to covey meta-messages.

Goal-based design pattern for delegation of work in health care teams

Adela Grando[a], Mor Peleg[b], David Glasspool[a]

Abstract

We show how a domain and language independent design pattern, defined as networks of tasks and goals, can be used to formally specify the transfer of responsibility and accountability when tasks are delegated in healthcare teams. The pattern is general enough to be applied unchanged across a broad range of different healthcare situations.

Keywords:

Clinical guideline, Goal, Design pattern, Medical error, Exceptions

Introduction

Clinical guidelines can contribute to the definition of better, safer, and more efficient evidence-based clinical care. Computer-interpretable guidelines (CIG) [1] can potentially increase the effectiveness of clinical guidelines by delivering patient-specific decision-support at the point of care. In general CIGs are defined in a particular language and lessons learned while developing them are difficult to share with groups working with other languages or different medical conditions. A possible answer is to specify generic solutions or *design patterns* [2] to recurrent common problems recognized in health informatics using a formal vendor-independent framework that allows sharing, reuse and study of patterns. The idea of creating a catalog of generic patterns that could be accessed and instantiated into particular problems using different languages has been previously suggested [3-5].

Healthcare processes, such as those modeled in clinical guidelines, are often carried out by teams. Incomplete or ambiguous specification of responsibilities and accountabilities in collaborative team work and the possible lack of accountability of medical staff working in shifts are important problems in healthcare [6, 7]. According to [8] "When delegating work to others, registered practitioners have a legal responsibility to have determined the knowledge and skill level required to perform the delegated task. The registered practitioner is accountable for delegating the task and the support worker is accountable for accepting the delegated tasks, as well as being responsible for his/her actions in carrying it out. This is true if the support worker has the skills, knowledge and judgement to perform the delegation".

In team work, delegation and assignment of tasks/goals is done based on the competences of the members of the team. During delegation, the responsibility for enacting a service and handling exceptions is passed from the requester (client) to a performer (provider); when the provider cannot cope with the exceptions he has to inform the client to transfer the responsibility. The accountability for the service outcome and exceptions arising during the service enactment is retained by the client [9].

We aim to tackle incomplete and ambiguous specification of responsibility and accountability in health care teams by formally specifying the transfer of responsibility and accountability in normal and abnormal situations during delegation of tasks/goals.

Methods

We formalize cooperative work in teams by extending a vendor-independent framework that we previously developed for specifying clinical design patterns [5]. We use the extension to define a generic pattern for delegation of tasks/goals that specifies levels of responsibility and accountability in normal and abnormal situations.

Framework for specifying design patterns for normal and exceptional behavior

In our framework [5] design patterns are specified as networks of tasks and goals (collectively termed "keystones") connected by scheduling constraints based on Petri Nets: all the incoming keystones need to be completed to enact the out coming keystone (AND join), the execution of only one of the incoming keystones is required to enact the out coming keystone (XOR join), all the out coming keystones are enacted after the antecedent keystone is completed (AND split) and only one of the out coming keystones is enacted after the antecedent keystone is completed (XOR split). As in the PRO*forma* model [1], tasks can be *decisions, enquiries, actions*, or *plans* (careflows comprising activities and goals). Goals represent temporal patterns of state variables which should be *achieved* or *maintained*. When a goal is active, a decision-support system proposes from a repository one or more candidate plans for satisfying the goal. Once the plan chosen for achieving a goal has been completed the goal is still active and its *successCondition* is checked to see if it has been achieved.

The framework allows abstraction of recurrent domain-specific scenarios as patterns, as well as abnormal scenarios originating from domain-specific or generic medical errors. Deviations from the expected process are abstracted using hierarchical definitions in a catalog of state-based exceptions, such that an exception is triggered when the corresponding state occurs, activating a goal-based pattern which abstracts commonly used strategies for repairing or recovering from the detected error. These strategies include invoking exception-handling flows and suspending or discarding affected keystones. The suspended or discarded keystones can revert to their previous state only after the exception-handling flow is completed. Exceptions are classified as hazards or obstacles. A *hazard* corresponds to a state that can *potentially* produce harm to the patient and an *obstacle* corresponds to a state where nominal execution of the guideline is not possible, either because the task cannot be completed or if its completion is no longer beneficiary to the patient.

Extending the design-pattern framework by specifying roles and actors

We extend the framework of [5] by proposing four new types:

type Role= <name, competences, restrictions, constraints>

Name uniquely identifies the *role; competences and restrictions* are sets of keystones that the *actors* performing the *role* can and cannot perform, respectively; *Constraints* are predicates that an *actor* must satisfy to play a *role*. For example to play the *role* of general practitioner (GP) the role player must be a registered practitioner. Role competence of health professionals is regulated by statues and professional bodies.

type Actor= <name, roles, competences, restrictions, attributes >

The *name* uniquely identifies the *actor; Roles* are set of *role* names that the *actor* is playing; *Competences* and *restrictions* specify those different from the ones inherited from the roles played by the actor. The sets of competences and restrictions should be based on the *actor*'s attributes. For instance in general nurses are not allowed to provide service X but nurse Ana can do it because she has taken a recognised course. Finally the *Attributes* are set of predicates that can be used to check if the *actor* satisfies the *role*'s constraints (e.g., has_degree_GP) or to select the actor for service delegation (e.g., based on the attributes experience, other_medical_specialities).

The competence, accountability, and delegation of services for some health registered professionals are regulated by statutes and regulatory bodies. In the UK regulatory bodies include the Nursing and Midwifery Council for nurses, midwives and health visitors, the Health Professions Council for physiotherapists, dieticians, speech and language therapists, and so on. Roles not regulated by statutes are accountable for their actions in three ways: civil law (duty of care), criminal law, and employment law. Therefore there are good sources of information that can be used to specify, in the way proposed above, the competences of the roles played by health care professionals. Once the *roles* and *actor* specifications have been completed the following functions can be used to determine (1) conflicts between two sets of competences and restrictions, (2) an actor's competence to perform a service (keystone), and (3) the set of actors who can provide a service for a client based on their competences and the client's constraints.

1. Boolean **function *areConflicting***(keystoneSet Compentences, keystoneSet Restrictions)=
```
{ If intersection (Competences, Restrictions)!=null
        then return true else return false;  }
```

2. Boolean **function *isCompetent*** (Actor actor, Keystone service)=
```
{ roleCompetences, roleRestrictions==emptySet;
 roles=actor.GetRoles() ;
  While roles!=null
  {  roles.GetFirst()=role;
     roleCompetences= union(role.GetCompetences(),
                                roleCompetences);
     roleRestrictions= union(role.GetRestrictions(),
                                roleRestrictions);
     roles.remove(role);
  }
allCompetences= union(roleCompetences,
                          ator.getCompetences());
allRestrictions= union(roleRestrictions,
                          actor.getRestrictions());
If not areConflicting(allCompetences, allRestrictions) &&
   allCompetences.contains(service) &&
   not allRestrictions.contains(service)
          then return true
          else return false;
}
```
An actor is competent to perform a service if and only if: there is no conflict between the restrictions and competences defined for actor and role, the actor is competent to perform the service (actor's and roles' competences satisfy the requirements for the service), and the service is not included in the actor's and role's sets of restrictions.

3. ActorSet **function *ObtainCompetentProviders***(Keystone service, Proposition constrains, ActorSet staff)=
```
{ providers=emptySet;
 While staff!=emptySet
 { staff.Retrieve()=staffmember;
   If isCompetent(staffmember, assignment) &&
      canSatisfy(staffmember, assignment, constraints)
         then
            providers.add(staffmember) ;
            staff.remove(staffmember);
  }
 return providers;
}
```

The function ***canSatisfy*** takes as arguments an actor, a service, and a constraint and it returns true if the actor can perform the service satisfying the constraints. Examples of constraints include time restrictions, place where the service should be provided, etc.

Each delegation starts with a service request:

type request = <client, provider, service, service type, satisfyCompletion, constraints>

Client identifies the agent that requires the service; *provider* corresponds to the agent that agrees to provide the service; *service* is the task that is assigned/delegated to the provider by the client; *service type* indicates the type of service requested and can take the values *assg, deleg, sdeleg* indicating assignment, delegation without supervision and delegation with supervision; *satisfyCompletion* is a function given by the client of an assignment to the provider to check if the service satisfies the client's criteria of service completion; *constraints* can be defined by the client to restrict the way the service should be provided. For instance the time constraint that the service should be provided in less than 3 hours.

If a provider accepts a service request a contract is defined:

type contract= < service request, startTime, finishTime>

Service request is the identifier of the service request that originated the contract; *startTime* is the date the contract starts; *finishTime* corresponds to the date the contracts finishes. Always *finishTime>startTime.*

Figure 1 shows the relationship between the new introduced types and the already existing types from the framework [5] used for the specification of the delegation pattern.

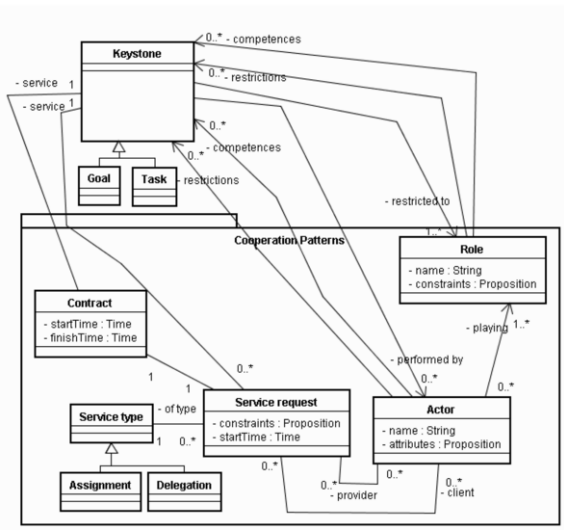

Figure 1- Class Diagram showing the connection between the terms used for the specification of the Delegation Pattern

Definition of service delegation

An actor called *client* delegates the enactment of a task or the achievement of a goal to a competent actor called *provider* such that:

Property 1. The provider is competent and responsible for providing the service.

Property 2. The client retains accountability for the service's outcome and any exceptions arising from the service enactment.

Property 3. The provider is responsible for handling any exceptions arising during the service enactment. When the provider cannot handle an exception the provider must transfer responsibility back to the client.

Property 4. The client is responsible for managing any exceptions that the provider cannot handle (whether detected by provider or client).

Design pattern for delegation of services

We define the delegation pattern based on formal approaches for delegation of tasks (services) between collaborative agents [10] from agent-oriented software engineering.

The delegation pattern is divided between the client's delegation workflow (Figure 2.1) and the provider's delegation workflow (Figure 2.2).

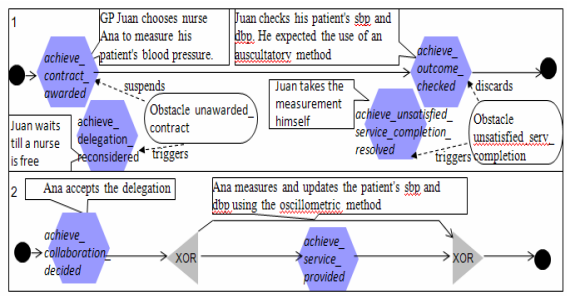

Figure 2- Delegation Pattern: 1) Client_delegation 2) Provider_delegation. In Figure 2.2 the first scheduling constraint corresponds to an XOR split, and the second constraint is an XOR join.

Table 1 contains the formal specification of the *Client_ delegation* workflow. As specified by the *precondition* of the client's workflow, a *service* can be delegated if the client has the competence to do so (according to function *isCompetent* the client can pursue the goal *achieve_ delegated*) and the service is not already assigned to another provider (there is no open *contract* and the service has not been requested according to *serviceRequest*). For instance the role general practitioner (GP) is competent to delegate the measurement of the patient's blood pressure to members of the hospital staff competent for that task, only if the same request is not being processed.

As shown in Figure 2.1 first the client tries to achieve the goal *achieve_contract_awarded*. For instance, the GP Juan can check the set of competent staff and delegate the task of measuring the patient's blood pressure to nurse Ana because she is available at the time he is requesting. In the exceptional case where no provider is willing to provide the requested service or a timeout has elapsed and no contract has been awarded, the discarding obstacle *unawarded_contract* is triggered, which discards the goal *achieve_contract_awarded* and triggers the

goal *achieve_delegation_reconsidered*. Thus Juan may decide to relax his delegation condition delaying the task to the first time when there is a nurse available.

In the best case a contract is awarded between client and provider (goal *achieve_contract_awarded*) and the client waits for service completion. In our example Juan can check the service completion by accessing the patient's record that contains the latest measures of the patient's systolic and diastolic blood pressure (sbp, dbp).

It may happen that after the provider has completed the service the client's criterion of service completion is not satisfied; in this case the suspending obstacle *unsatisfied_service_ completion* is triggered. For instance, Juan specified that he wanted to have his patient's blood pressure measured using the auscultatory method, but according to the patient's records the measurement has been done by an oscillometric method. The obstacle *unsatisfied_service_completion* suspends the goal *achieve_ outcome_checked* and triggers the goal *achieve_unsatisfied_ service_completion_resolved*. In our example Juan decides to make an appointment with the patient to take the measurement himself.

Client Juan is responsible and accountable for both exceptions *unawarded_contract* and *unsatisfied_service_completion* because they happened before and after the service enactment, respectively. If any exception had happened during the service enactment nurse Ana should be responsible for dealing with it.

The workflow *Client_delegation* is completed when the goal *achieve_outcome_checked* is achieved and, as described in Table 1, the contract between client and provider has been closed, and the client's completion criteria is satisfied.

Table 1- Client_delegation

Attribute	**Client_delegation**
Parameters	service, contracts, staff, preferences, isComplete, serviceRequests
Precondition	isCompetent(actor, achieve_delegated((service, contracts, staff, preferences))) & not contracts.contains(service, anytype, actor, anyProvider, start, null) & not serviceRequests.ObtainAll(). contains(this.GetActor(),anyProvider, service, anyType)
Success Condition	ObtainProviders(service,preferences,staff). contains(provider) & contracts.contains (service,deleg, this.GetActor(),providers,start, finish) & isComplete (service.GetSuccessCond())

We now turn to the provider's workflow in the delegation pattern (Figure 2.2). For the sake of brevity we do not provide the formal specification for the provider's workflow. The provider's workflow is activated when an actor receives a request for service delegation from a client and there is no contract between the client and any provider for this service. The provider decides whether he wants to collaborate, in which case he satisfies the goal *achieve_collaboration_decided*. If he does not want to collaborate the provider's workflow ends without activating the goal *achieve_service_provided*. For instance Ana receives a request from Juan to make an appointment to measure a patient's blood pressure at a time she is available. Ana is competent to perform the task so she accepts the appointment. If as in this example the provider accepts the *achieve_contract_awarded* is achieved, the provider's first goal is achieved and the provider's second goal *achieve_ service_ provided* is activated. The provider's workflow finishes when according to his completion criteria the service has been completed. The provider's criteria for service completion are not necessarily identical to the client's criteria for service completion. For example for Juan the blood pressure should be taken using an auscultatory method, while for Ana the task is achieved when any accurate measuring method is used. Because of possible differences between the client's and provider's completion criteria after the workflow *Provider_ delegation* has been completed the contract between client and provider is still open until the client checks that the service's outcome is the desired one (goal *achieve_outcome_checked*).

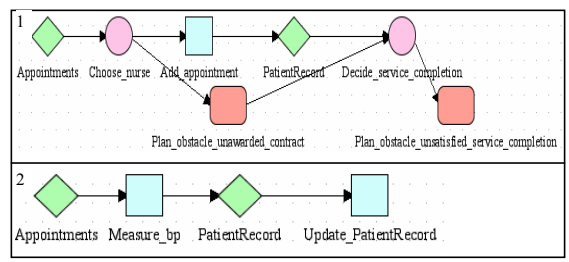

Figure 3 - Implementation of the delegation pattern in the Tallis toolset.

Results

Properties satisfied by the pattern

Property 1: In the case of the client the pattern is defined in terms of the goal *achieve_contract_awarded*. Therefore providing the service has not been assigned to anyone else, the provider is *competent* to provide the requested service and accepts the delegation (as specified by goal *achieve_ collaboration_decided*) then a contract is opened between them, which makes the provider *responsible* for providing the service.

Property 2: As specified by the delegation pattern, the goal *achieve_outcome_checked* is part of the client's workflow, therefore he checks that his completion criteria is satisfied after the provider has finished the delegated service. Only if the client's completion criteria are satisfied is the delegation contract between the client and provider closed. Because a delegation contract is signed between the client and the provider when the goal *achieve_collaboration_decided* is achieved, the client becomes *accountable* for any exception arising from the service enactment.

Property 3 can be proved only if the following property is satisfied by the catalogue of exceptions provided by the exception manager:

Property to be satisfied by the catalogue of exceptions: *Each exception from the provided catalogue is specified such that the actor responsible for meeting the goal that was triggered in order to handle the exception is the actor who enacted the keystones or goals that triggered the exception.*

For any catalogue of exceptions provided for the patterns this property must be checked.

Property 3: If the repository of exceptions satisfies the property explained above then the provider is responsible for enacting exceptions arising from the service enactment. But in case the provider cannot cope with the exception he can inform the client and transfer to the client the responsibility of dealing with the exception. A hazard can be triggered to inform the client about the exception and the recovery strategies that he has unsuccessfully tried.

Property 4: When the provider achieves the goal *achieve_exception_informed* the provider has been informed about the unresolved exception which arose during service enactment and responsibility for enacting a plan to recover from the exception has been transferred the provider. Once the provider has been informed about the unresolved exception he can activate the goal *achieve_exception_recovery_decided.*

Pattern enactment

Design patterns have proved to be very powerful generic and abstract mechanisms for software analysis, design, and comparison, provided they can be mapped to concrete executable languages. In Figure 3 we show an implementation of the delegation pattern in the Tallis[11] toolset used for enacting PRO*forma* guidelines. Each component from the delegation pattern is mapped into one or more Tallis components. Figure 3.1 corresponds to the *Client_delegation_pattern*. To pursue the goal *achieve_contract_awarded* the GP starts querying the existing appointments (query *Appointments*) and chooses an available nurse (decision *choose_nurse)* to delegate the task of measuring his patient's blood pressure. When a nurse is chosen a new appointment is created (action *add_apointment*). Both GP and nurse roles and the actors playing those roles are specified as described by the types *Role* and *Actor* that we introduced to extend the design-pattern framework. To satisfy the goal *achieve_outcome_ checked* the GP activates the action *check_patient_bp* after the appointment date. Possible exceptions are: the case when no nurse is free, which activates the plan *Plan_obstacle_unawarded_contract;* or the case when the service has not been completed according to GP's requests, which activates the plan *Plan_obstacle_unsatisfied_ service_ completion*. Figure 3.2 corresponds to the plan *Provider_ delegation_ pattern.* In this hospital the nurses cannot refuse to take appointments, therefore the goal *achieve_ collaboration_ decided* is always satisfied after the GP chooses a nurse. The provider's plan starts when the nurse pursues the goal *achieve_service_provided* by taking the blood pressure measurement the date chosen for the appointment (query *Appointments* followed by action *measure_bp*). The delegated service is completed when the patient's record is updated with the measurement (query *PatientRecord* followed by action *update_ PatientRecord*).

Discussion

The delegation and assignment patterns have been enacted by mapping them into the Tallis tool used for running PRO*forma* guidelines. In addition a simplification of the patterns, which does not include exception detection and recovery, has been implemented and enacted in a COGENT prototype. What remains to be done is to fully explore the practical benefits of the use of these patterns, by mapping them into a real clinical-based application.

Abstract

Healthcare information systems are accused of poor usability even in the popular media in Finland. Doctors especially have been very critical and actively expressed their opinions in public. User involvement and user-centered design methods are seen as the key solution to usability problems. In this paper we describe a research case where participatory methods were experimented within healthcare information systems development in medicinal care in a hospital. The study was part of a larger research project on Activity-driven Information Systems Development in healthcare. The study started by finding out about and modeling the present state of medicinal care in the hospital. After that it was important to define and model the goal state. The goal state, facilitated by the would-be software package, was modeled with the help of user interface drawings as one way of prototyping. Traditional usability methods were extended during the study. According to the health professionals' feedback, the use of participatory and user-centered interaction design methods, particularly user interface drawings enabled them to describe their requirements and create common understanding with the system developers.

Keywords:

User interface design, Interaction design, Usability, User requirements, Participatory design, Medicinal care

Introduction

This paper describes a research case where a few traditional usability methods were used to specify end-users' requirements in the demanding context of medicinal care. At the same time the methods were further developed to fit better with domain of healthcare information systems (IS) development. The researchers were user interface and interaction design professionals with a strong background in industrial art.

Health services are an information-intensive field across the world. A huge amount of information in different forms is constantly needed by various professionals to support their work. A range of software products, as well as traditional tools for information processing and communication, are utilized. The quality of these tools varies and not all of them support the actual work processes or mutual aims in this highly complex environment. There is a great deal of available health information management software. However, doctors and nurses are still using traditional paper forms, for example, for planning and following up on medicinal care in university hospital units.

According to the public discussion in Finland, healthcare professionals are dissatisfied with current tools, such as patient record systems and other software products. Doctors and nurses are complaining that current software products do not help them enough with their everyday work with complex patient data. [1,2]

Even the most common tasks take too long and are illogical to complete. It seems that the users' point of view has been ignored and the usability of the systems has not been tested before implementation. Particularly, doctors have been very critical users and they have actively expressed their opinions in public, for example, in the Finnish Medical Journal [1- 3]. Problems in the usability of clinical information systems are also known world wide [4].

User participation in information systems development is considered to be an answer to usability problems. According to the ISO standard 9241, usability is "*the extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use*" [5].

Participatory Design (PD) is an approach to designing technological and organizational systems that attempts to actively involve workplace practitioners, future users of the system, in the design and decision-making processes [6].

Interaction Design (IxD) defines the structure and behavior of interactive products and services. Interaction Designers create compelling relationships between people and the interactive systems they use [7]. Design practices typically alternate between user research, analysis, and actual design work.

There have been only rather few studies in the healthcare IS world using usability methods [8]. But a result of these studies confirms that usability methods are also effective in the healthcare domain [9, 10]. More often usability methods are used in consumer product development such as mobile phone software and computer game development.

Smelcer et al. have argued that "usability work with EMRs is not straightforward":clinicians use foreign terminology, there are different specialties in medicine, and every specialist has different needs for using EMRs [4]. Also, observing clinicians' work is challenging because of privacy regulations [4].

The development of healthcare information systems differs from the development of consumer products. The main differences to mainstream usability studies are:

- The end-users are not those who purchase products, which can cause problems, especially when developing the usability aspects of products.
- Some usability methods, e.g. observations in actual patient care situations, are difficult to use because of the confidentiality of patient records.
- The context of use of software products is highly complex. Physicians' workflows are difficult to understand without medical education.
- The new products are usually only one part of the larger (hospital) IS infrastructure, not "independent products."

Medicinal care in hospital units is based on co-operation between the patient, physicians, nurses, and other professionals. At its best, medicinal care crosses the dividing lines between units and organizations. Medication information should be available in various care situations. It is an important part of electronic patient records and it is crucial that the information is up to date.

Information systems for keeping the patients' medicinal care up-to-date (medicinal information systems) need to be integrated with many other EPR products in Finnish hospitals. This will bring challenges to the IS and usability development.

Objective and research questions

The primary goal of the research was to experiment with how the participatory, usability, and interaction design methods would work in the field of user requirements specification for healthcare software.

The usability methods to be experimented with were heuristic analysis with end-user participation, observations combined with simulations, artifact analysis, contextual inquiries and analysis, and prototyping with use cases.

The more detailed research questions were:

- How can the end-users' requirements and needs for the healthcare software be collected?
- How can end-users be involved in the software development process?
- How can common understanding on the future software be achieved between developers and end-users?

There was a need to find out how to specify health information systems for both software engineers and healthcare professionals to understand the future software. The study started from the premise that user interface drawings could be a base of shared understanding and would be a good method for defining user requirements. This requires more than an ordinary software developer's education to design the future product as well as the future software user interface. Designerly knowing skills are needed. [11].

Materials and methods

The research case was carried out as part of the ZipIT project, the aim of which was to narrow the distance between the different worlds of work improvement and information system development. The project produced the Activity-driven Information Systems Development (AdISD) model [12, 13].

The research case presented in this paper was called: "Planning and following up medicinal care in hospital wards." The researchers participated in the work of the medicinal care documentation development group of the Finnish hospital. The group consisted of healthcare professionals, physicians, nurses, and pharmacists. The primary working method of the group was workshops. The group was established because of end-users' poor experiences with the medicinal care software that had been in pilot use in the hospital. The users found that the software was inappropriate for use in real-life patient care situations and, with the software, patient safety issues could not be assured. The primary goal of the work group was to produce development ideas for the new version of that medicinal care software.

The empirical research work can be divided into four phases. Firstly, there was a need to find out about and to model the present state of medicinal care. Secondly, the goal state was defined. The third phase consisted of modeling the use of the would-be software package in the goal state with the help of user interface drawings. Finally, feedback was gathered from the end-users.

Present state survey

To understand the present state, it was important to become familiar with the literature of the basic principles and terminology of medicinal care and care processes. An experienced nurse was interviewed to achieve a more concrete understanding of the medicinal care system in the hospitals. Based on those actions, the acquisition of information, a flowchart of medicinal care in a hospital unit was drawn. The nurse also reviewed the flowchart.

The researchers also found out about how software development of healthcare systems in general had been done. Specialists were interviewed about the common methods of user involvement. According to those specialists, the end-users participated in workshops organized by software providers; no other participatory methods were used commonly.

To identify the usability problems of the existing prototype of the medication information system, heuristic analysis was carried out with user participation. After the analysis, users rated the findings. It was impossible for the researchers to perform the severity rating of the standard heuristic evaluation method because usability problems were deeply involved with the users' tasks. The analysis and rating built an atmosphere of trust with the end-users and removed prejudices against researchers.

To researchers the purpose of the early workshops of the medicinal care documentation development group was to collect information and verify their understanding of medicinal care in

hospitals. The results of the analysis of the information from the workshops were different kinds of data structure charts. This analysis phase can be called data analysis and an Affinity Wall was used as a working method from Contextual Design, a user-centered design process developed by Karen Holtzblatt and Hugh Beyer [14].

The researchers figured out what data the physicians needed for making decisions about the patients' medicinal care. The users' goals in that data processing were also determined.

In between workshops participatory observations, interviews, and simulations of both manual and digital systems were conducted in the hospital wards. The observations were related to medicinal tasks, e.g., doctors' rounds and nurses' medicinal preparations and deliveries. These were documented by photography and taping. It was also important to collect empty and used paper forms that were used in the medicinal tasks, for artifact analysis: "*Artifact analysis may be used to supplement observational data and to gain a more thorough understanding of people's tasks, and may lead to the design of improved artifacts*" [15].

A member of the hospital development group modeled the present workflow of medical care in the hospital. The flowcharts were drawn from the patient's point of view (care pathway). The researchers noticed that there was also a need to describe the end-users' processes, e.g., physician process, nurses process, etc. It was very important to find out which points of the workflow professionals needed information about a patient's medications. Modeling those workflows produced the understanding of work activities in the hospital. It is important to know the entire work activity in order to understand a specific part of it.

After finding out about and modeling the present state, it was possible to define user needs and design challenges. For instance, when writing a prescription, a doctor must be able to see every piece of information related to the patient, not just medicinal notes. Both doctors and nurses have to see medicinal notes in a chronological order; they must be able to write medicinal notes, riffle through previous notes, and document the prescribed and given medicine. These basic requirements were detailed during the design process.

Goal state survey

The primary aim of this phase was to describe the human-computer interaction and user experience with the help of use cases and user interface drawings. The researchers wrote use cases with the help of Laakso's model [16]. The written use cases were goal-based use cases because writing the use case without a goal does not generate enough information for interaction and user interface design.

Each written goal-based use case described one work task and all the information needed for making decisions concerning that work task. It was important to separate those facts that the user already knew from those that the user needed to know.

Interaction design and user interface design

The user interface (UI) and interaction design process itself was interactive. Briefly, the users' needs for medication information were discovered and the user interface was designed to service these needs. All user interface design solutions were discussed with the users in workshops, and corrections were made as needed. This can be seen as low fidelity or paper prototyping [17, 18].

This process made it possible to define almost all of the user requirements with user interface drawings or a series of drawings.

It was important to design the UI drawings with real patient data. In this phase, the previously collected and analyzed artifacts and the workflow charts that included the medication data were very important. The researchers produced series of user interfaces based on the user workflows. The user's interaction with these series of drawn UIs was tested with the help of the goal-based use cases. This made it possible to avoid the worst design mistakes.

The design principles that emerged for the medicinal information system are as follows. What physicians need to see to be able to decide on how to continue medicinal treatment (and what was lacking in the previously existing system): all of a patient's medications; changes in medication, medication history; current medication and planned changes (e.g., operation day). All of these must be confined to time. The problem with the previously existing system was that it did not have enough support for the user to understand the relations between medication and time.

The drawn UI proposal was split into three parts. The first part was patient information because of patient identification and the need to see critical information in some care situations. Afterwards the researchers realized that the designed proposal followed one of the main principles of MSCUI: "*Correct identification of a patient and the matching of a patient to their care elements*" [19].

The second part, in the middle of the user interface design, was a view of the actual medication list. This view was combined with a calendar view. The calendar view was split into two parts, daily and weekly. Below that there was the third part, a row of information on the history of a selected medication. This three-part solution appealed to the users.

Feedback gathering

After the research, feedback on the working process and the methods was gathered from the end-users who participated in the work. The feedback gathering was done with the help of a web-based questionnaire form. Every respondent thought that it was very useful to model the collected user needs as user interface drawings. The expressed thoughts and needs for the software were seen immediately in the user interface drawings.

To that point, the work of the researchers was completed and the development of the medicinal care software continued in the product development team of the software provider.

Results

The results of this research can be divided into two groups: practical user interface proposals and methodological results.

We were able to define medicinal care user requirements with user interface drawings or a series of drawings, as expected. We also developed standard usability and user-centered design methods to fit better with the demanding field of medicinal information system development.

Graphical user interface proposal

The graphical user interface proposal came about through the process of developing an effective communication tool between all participants of the required specification team. The user interface drawings were an unambiguous way to see how the future software was supposed to look and feel. With the help of those drawings, it would also be possible to check whether or not the specified system will support the users' goals.

Methodological results

According to this research case, standard user-centered design and usability methods seem to be suitable to complex medicinal information system development, too. Putting those methods into practice in this field, however, demands a lot of collaboration between end-users and developers to ensure that the healthcare professionals' needs are taken into account properly.

In addition, it was realized that the end-user working process is very different from the patient process. Doctors and nurses are normally repeating some small piece of the patient process throughout their work day with different patients, but current software development methods are not taking this into account. Understanding the everyday work of clinical practitioners with several patients at the same time is an important, but often ignored, starting point for the development work.

During the project, the researchers developed two extensions to existing usability methods:

1. **Heuristic evaluation with end-user participation**. Instead of the evaluators rating the severity of the usability findings by themselves, the researchers organized a web survey to collect the professional end-users' opinions on the severity ratings. In that way, it was possible to cover the professionals' point of view and it also helped the researchers to build an atmosphere of trust between the interaction designers and the clinical professionals.
2. **Method to conduct simulation workshops with professional end-users**. The end-users prepared themselves for the simulation workshops by bringing real patient data with them (without personal information). During the workshop we simulated how the designed user interface would work with that data and we discovered several possible patient safety and usability issues to be corrected during the next design iteration. It was a cost-effective way to validate the planned user interface solutions with real patient data. This method also gave us a good understanding of the co-operation between physicians and nurses.

Lesson learned

Afterwards we realized that there should have been two more phases of the development process after where we stopped:

First, the user interface drawings and the prototype developed on the basis of the drawings should have been tested with the help of end-users. To get valid results, the end-users should not be the same ones that participated in the development group, because the latter already knew too many of the compromises and decisions made in the development phase.

Second, after careful usability testing, the interaction designers should have provided usability support to the developers; there seems to always be a need for compromises between the usability objectives and technical limitations in the development phase. If the same designers take care of the implementation compromises, too, this prevents any big new usability problems.

Discussion

The results were quite similar to other research in this subject area. Complex design problems require more knowledge than any single person possesses. Participatory and collaborative design methods are useful in producing a shared understanding of the target area and can lead to favorable and unexpected ideas and solutions.

Nowadays there is a huge amount of data in health records; the problem is not data input, but the access to the relevant information in the right situation in the right format. To understand better what information needs to be seen when and how, we need a better understanding of the users' work tasks and work flows and the information they need in various care situations.

It is hard to develop only one part of a large information system without a really good understanding of the entire picture. Users in hospitals have to work with many types of software and these software products should be integrated well enough to support the whole work path of the user. That cannot take place through technical integration only, it has to be "logical" integration. System developers should study the users' work. The developers' world is too different from the hospital environment. Doctors do not sit next to the computer in the same place all day. They do rounds and visit patients' rooms and operating rooms. They handle the data of lots of different patients at the same time – their work is not like a "logically" ordered timetable.

With this specific research case, the researchers were able to confirm the ideas of participatory interaction design, describing user requirements in a more efficient and understandable way with user interface drawings. Common understanding between designers and end-users was achieved through the user interface drawings. Without seeing user interface drawings – the first prototype of the future software – it is hard for users to participate in requirement specification. Continuous usability testing throughout the design process is needed to ensure that the process moves into the right direction.

User participation is very important, but almost as important is the way how the users are involved. Listening to the end-users is the most important thing, but it is crucial to keep in mind that they are not designers. By presenting some ideas, users typically point out problems even though their design solution might be insufficient. This is a good starting point for developing new

methods for collecting and verifying user needs and requirements in healthcare information systems development.

Conclusion

In this paper we reported on an experiment in applying participatory interaction design methods in healthcare information systems development in medicinal care in a case hospital. The process and the results of four phases of the case study were reported: (1) modeling the present state; (2) defining the goal state; (3) modeling the use of the would-be software package in the goal state with the help of user interface drawings; and (4) gathering the feedback from the end-users.

The results show that participatory and collaborative design methods are useful when aiming for usability in the complex domain of healthcare. Systematic further research is required to develop practicable methods for system developers.

Cognitive Evaluation of a Physician Data Query Tool for a National ICU Registry: Comparing Two Think Aloud Variants and Their Application in Redesign

Linda W. Peute, Nicolette F. de Keizer, Monique W. M. Jaspers

Department of Medical Informatics, Academic Medical Center – University of Amsterdam, The Netherlands

Abstract

Applying usability methods in formative evaluations of interactive healthcare information systems design is recognized as of extreme importance to the final success of these systems. However, it seems that the merits of specific methodological approaches for conducting these studies have received little attention. This study reports on a cognitive evaluation of a Physician Data Query Tool, which offers physicians the opportunity to query quality of care data collected by the Dutch National Intensive Care Evaluation (NICE) foundation. A comparison in terms of usefulness and utility of two variants of the Think Aloud method is addressed, the Concurrent and Retrospective Think Aloud. These methods are well known in the field of Human Computer Interaction in the context of usability evaluation. The results of this research indicate that though both methods have their disadvantages and benefits, in redesigning the Physician Data Query tool the Retrospective Think Aloud provided more useful input to the Tool's redesign. However, in deciding which method to apply in a formative evaluation study, end users' cognitive workload of performing the system's tasks and the system characteristics need to be considered as well.

Keywords:

User-Computer Interface, Usability Study, Cognitive Evaluation, Health Care Quality Evaluation, Physician Data Query.

Introduction

Understanding the cognitive processes of clinicians, such as the processes by which they (learn to) comprehend and interact with interactive programs, is a prerequisite for building tools that support clinical practice in an appropriate manner [1]. The think aloud method is generally recognized as a major source of data on subjects' cognitive processes and has been applied in studies on computer program comprehension in the field of Human-Computer Interaction (HCI) for decades. Its application in usability testing of health information systems aims to improve clinician system interaction and to develop more usable interfaces [2]. Ericsson and Simon (1984) have presented two variants of the think aloud methods which have been applied in the context of usability testing in recent years; Concurrent (CTA) and Retrospective (RTA) Think Aloud [3,4]. When applying the CTA method, subjects are instructed to verbalize their thoughts while conducting a task. In contrast, the RTA method instructs users to recall their thoughts or actions after they have finished the task by for example reviewing a video recording of their actions. Analysis of the verbal protocols and video recordings has the purpose of revealing the contents of the subject's working memory and his corresponding action, thus providing a unique insight into the subject's cognitive processes in relation to experienced system usability. Controversy exists, however, about the utility and validity of these two methods in usability testing of interactive health information systems [4,5]. It seems that the choice of application of these methods should be based on the nature and complexity of the task to be performed by the subject [4]. Also, which method best to apply in a formative evaluation study of an interactive health information system is still unclear.

This paper explores the use and utility of both the Concurrent (CTA) and Retrospective (RTA) Think Aloud method in a usability study of a Physician Data Query Tool for a national ICU quality of care registry in the Netherlands. We address a comparison of the methods in task completion time and task performance with tasks of differing cognitive difficulty, and type and number of usability problems detected. We discuss the implication of these results for system redesign in general and in light of the efforts that are currently undertaken in redesigning the Physician Data Query Tool.

Materials and Methods

Test object: NICE Online, a Physician Data Query Tool

In 1996 the Dutch National Intensive Care Evaluation (NICE) foundation started collecting data on patients admitted to Dutch ICUs. The NICE database, also called NICE registry, contains information on demographic, physiological and clinical variables required to calculate mortality risk predictions according to the Intensive Care prognostic models [6]. The NICE registry aims to detect differences and trends in quality and efficiency of ICU care and provides quality reports and benchmarking information to its participating hospitals on a quarterly basis. In 2004 the request was made by participating hospitals if the NICE database could be queried by them to answer more specific clinical questions for their own ICU management or scientific reporting. To provide participants with the opportunity to query the NICE database

while protecting the privacy of the participating hospitals, a Physician Data Query Tool called **NICE Online** was developed in 2004 by a group of software engineers.

A standard software design cycle was applied in this project with the primary focus to develop a graphical interface for querying purposes. The user's view on query commands was reduced to a designer-customized browser, with a structured query model (figure 1) to support clinicians in developing queries, assuming that they have no or little experience in database query command development.

Figure 1-Screenshot of the Physician Clinical Data Query Tool: NICE Online.

Nice Online can only be used by participants with a user account. When entering the system, a large list of 'standard queries' is presented to the user. He/she can decide to select one of these queries and directly view the query's resulting table or graph or he/she can chose to change the query by adding (data) elements to the query model. Another possibility is to start a new query, also called 'custom query' in the system. A user is then presented with a blank query model, in which he/she must add all (data) elements needed for the query. The query model consists of four components: functions, splitting/intersection, benchmarking/mirror and selection of subpopulation. For each component the user can select from a large list of elements that are either statistical models or data elements collected by the NICE Registry. For example, functions are Intensive Care prognostic models which may form the basis of a clinical query. 'Benchmarking' refers to at least the user's 'own hospital data' for example in comparison to the element 'national data'. The splitting/intersection and selection of subpopulation components offer the user the possibility to split the data for example in gender categories or to create a subpopulation with regard to for example a certain time period. When a user is finished with the query model, he/she can select the 'graph/table' button to create the resulting graph or table.

Not all participants have yet requested a user account of NICE Online. In July 2008, NICE Online registered 80 users. A log file analysis, performed to gain insight into NICE Online usage patterns, showed that only 17% of the participants with a user account actually used the query functionality on a regular basis. Telephonic information needs analysis provided insight into user experiences with NICE Online. It showed that users were willing to use the tool but the structured interface for query development was not appreciated by them. However it did not become clear in what way the cognitive burden of a query development by use of the Tool was influenced by a potential lack in the Tool's usability. Next to this, planned expansions to the NICE Database, such as the collection and reporting of structure, process and outcome quality indicators of ICU's, required a high level of user-friendliness of NICE Online, which made it necessary to redesign the Tool and improve on its usability.

Subjects

Our study involved 16 subjects. Subjects were categorized on basis of a log file analysis of NICE Online usage patterns in order to select a number of representative target users. Subjects were assigned to one of the two conditions in a matched-randomized way with tool experience as matching factor. For testing of the Physician Data Query Tool formal agreement to contact the users was given by the NICE Foundation. The selected subjects were then contacted by email with an accompanying letter. All agreed to participate to the NICE Online evaluation study.

Tasks

To evaluate the cognitive workload and the usability of the Physician Data Query Tool (NICE Online), six tasks were developed which were divided into two to six smaller subtasks. Input into the development of these tasks was given by two data managers of the NICE Foundation. They where highly experienced in ICU clinical query development and were able to provide generally relevant tasks of varying difficulty with a golden standard for how to perform and finalize each task. The tasks were preceded by a query description, or short clinical question, which could be answered by data in NICE Online. The usability test started with two standard query tasks, randomly given. These tasks provided the subject with some experience in NICE Online, and for the CTA method it provided participants with practice in verbalizing their thoughts while performing a task in the system. Then four tasks were randomly presented to the subject with a varying degree of difficulty. These four tasks consisted of two custom query tasks, in which the user had to enter a query statement as described in NICE Online, and two tasks consisting of a clinical question to be translated into a query in NICE Online. An example of both tasks is given in Table 1.

Table 1- Examples of the usability Tasks

	Examples Main question
Custom query task *easy*	*'Please select the percentage of patient admissions which are split by admission type for the data of your own hospital within a sub selection of the last two years'*
Translating a clinical question task *easy*	*'The annual NICE report shows you that there exists a difference in the mean length of stay for patients in the age category 60 to 70 year in the year 2007 compared to 2008. You whish to find out if this is correct by making a graph of these data in NICE Online.'*

CTA and RTA experiment

The experiments took place in the actual clinical working area of the subjects. A portable usability laptop with Morae software made it possible to record all the subjects' verbalizations in combination with a screen recording of their (mouse) actions in the system and a video recording of the subjects performing the actual tasks in NICE Online on the usability laptop. In both the CTA and RTA condition, the experimental procedure started with the subject answering questions about his or her general computer experience, experience with statistical knowledge and calculations, and experience in formulating queries in other systems. Hereafter the subject received the tasks as well as oral instructions on how to carry them out on the laptop. In the CTA condition, the subject was instructed to think aloud while performing the tasks. In line with the Think Aloud procedure described in [3], it was made clear that the accompanying researcher, the facilitator, would not interfere with the session by giving assistance, but would only remind the subject to keep thinking aloud if the subject would fall silent for a while. Finally, the subject was told that the goal of this test was to gain insight into the problems he/she might encounter in using NICE Online, and to understand in what way he/she translated a clinical question to a NICE Online query. In the RTA condition, the subjects received the tasks and short oral instructions. They were instructed to carry out the tasks in silence on the laptop, without assistance of the facilitator. After the session, video recordings of their actions in the system were shown to them and they were asked to verbalize their thoughts retrospectively. The analysis of the think-aloud sessions was done in the Morae Manager from Techsmith. Additional validation of the subjects' task performance was performed by the research and database manager of the NICE Foundation.

Results

General results

The 16 experiments resulted in over 24 hours of recordings. The CTA testing lasted approximately 1 hour, while the RTA testing lasted about 2 hours, including the time for retrospective reporting. The transcription of the verbal protocols of subjects in the CTA condition resulted in 3 times as much data compared to the transcription of the verbal protocols of subjects in the RTA condition. Of the subjects, 12,5% was female. Of all subjects 62,5% mentioned that they considered themselves expert with regard to computer experience, 50% considered themselves expert in statistical calculations and 56,25% regarded themselves expert in query development. The analysis showed that subjects who considered themselves as experts were somewhat equally divided between the two methods.

The verbal protocols of subjects were transcribed and all actions of subjects were linked to the comments made by them as reflected in the protocols. Two analysts went through all verbal protocols and video recordings and separately coded the usability problems, experienced by the subjects, in usability categories described among others by Kushniruk et al. [7]. Inter rater reliability was measured by Cohen's kappa (.83) which constitutes to a substantial agreement between the two analysts. In total 43 singular usability problems were analyzed.

Task completion and performance

Table 2 shows a comparison of the CTA and RTA method with respect to 1) task completion time in minutes and 2) task performance in terms of incorrect tasks (N/E) per difficulty level. Analysis showed that development of a custom query in the system took slightly more time in the CTA condition than in the RTA condition. Yet, there was only one clear difference in task completion time between the two methods. The translation of the clinical question to a query in NICE Online in the easy category took exceedingly more time in the CTA condition than the RTA condition. Also, this task was more often performed incorrectly by subjects in the CTA than in the RTA condition. Analysis of the verbal protocols revealed that subjects in both conditions experienced much difficulty in translating a clinical question to a query in the Tool and commented on this task to be cognitively complex. This translation proved however more difficult for subjects in the CTA condition than in the RTA condition. In total, 24 tasks were incorrectly performed in the CTA condition whereas 12 were incorrectly performed in the RTA condition. Overall, the CTA condition had lower task performance than the RTA condition.

Table 2 - Overall task completion time in minutes, N/E tasks not executed correctly

	CTA			RTA		
	Mean	**SD**	**N/E**	**Mean**	**SD**	**N/E**
Standard Query						
Easy	4.8	1.8	1	5.0	0.3	0
Difficult	7.3	1.8	2	6.9	2.0	0
Custom Query						
Easy	6.1	0.1	3	4.5	0.7	2
Difficult	7.5	2.0	4	6.8	2.1	3
Translating Question Query						
Easy	11.3	1.8	5	7.5	0.8	2
Difficult	11.7	0.9	9	9.4	3.3	5

Usability problems

Table 3 gives an overview of the mean number of usability problems detected for each usability category per think aloud method. Table 3 also shows the number of problems per category that was uniquely detected by one of the two methods (CTA or RTA) and those problems that were detected in both the CTA as well as the RTA condition. The CTA condition provided insight into several types of usability problems. Analysis of the verbal protocols revealed that subjects in the CTA condition, when confronted with usability problems of a minor or cosmetic nature that directly obstructed the performance of a task, directly commented upon that issue. In contrast, the verbal protocols of subjects in the RTA condition showed that subjects did not report upon

these minor usability problems. Instead, subjects' comments in the RTA condition focused more on the complex usability issues they had experienced during the test.

Table 3 - Usability problems per category and total number of problems per think aloud method.

Problem types	CTA		RTA		CTA	RTA	Both
	Mean	SD	Mean	SD	#	#	#
Navigation	4.9	1.2	4.2	1.1	2	0	3
Graphics/ symbols	5.6	1.8	3.4	0.5	4	2	2
Layout/screen organization	4.8	1.4	2.9	0.8	2	0	4
Meaning of labels/ terminology	5.0	0.5	7.2	1.2	0	4	4
Error messages/ help instructions	4.9	1.7	4.7	1.4	2	0	3
Overall ease of use	6.0	2.8	4.1	1.2	1	1	6
Visibility of system status	3.8	1.5	3.2	1.1	1	0	2
Total number of usability problems	36.0	-	31.0	-	12	7	24

Overall, it can be stated that the CTA condition revealed more usability problems than the RTA condition. The RTA method however provided more usability issues concerning the terminology and meaning of labels. Also, the verbal protocols of subjects in the RTA condition, subjects' verbalizations proved more explanatory towards these problems. For example, one subject in the CTA condition did not completely understand what the term splitting/intersection meant in the query model, he showed irritation and commented there upon, while the subject in the RTA condition explicitly described what the problem was, and how to resolve this terminology issue, which was of high importance to redesign of NICE Online. The analysis of the CTA and RTA verbal protocol data showed that subjects' verbalizations in the CTA and RTA method differed considerably. The golden standard for task completion provided by the NICE data managers proved useful in analyzing the verbal protocols of subjects. When tasks were commented upon by subjects in one of the two conditions, the numbers of statements made by a subject was classified in terms of 'experienced Tool usability', 'explanatory Tool usability', 'task statistical reasoning', 'task comprehension', and 'task query complexity' and were subsequently counted. The verbal protocols showed that comments made by subjects' about 'statistical reasoning', 'comprehension of the task' to be performed, or comments made about the 'complexity of the query' were of a different cognitive nature then the comments made on the experienced Tool usability. Table 4 shows the mean number of these 'cognitive' problems detected per method. In the CTA condition during the usability test subjects explicitly verbalized when they did not fully comprehend a statistical model or the task to be performed or the query to be made in the Tool. Subjects in the RTA condition did not comment upon a potential lack in their statistical knowledge, or in their (in)comprehension of the task at hand.

Table 4 – Mean number of statements of a cognitive nature per method

	CTA		RTA	
	Mean	**SD**	**Mean**	**SD**
Problems in statistical reasoning	5.3	1.0	1.0	1.1
Problems in task comprehension	5.1	1.7	2.3	1.2
Problems in query design complexity	5.1	1.4	4.5	2.2

Discussion

This study shows that task completion in the CTA condition for standard and custom query tasks did not take more time than task completion for standard and custom query tasks in the RTA condition. The task of translating a clinical question to a query in NICE Online took generally more time in both methods, but took exceedingly longer in the CTA condition than the RTA condition. In the Human Computer Interaction literature it is under debate if the CTA and RTA methods offer similar results in terms of task completion time [8,9]. The results of this study seem to indicate that subject's task completion time in the CTA method is influenced by the task complexity. Apparently task completion time of the translation of a clinical scenario to a query seemed to be affected by the cognitive workload of both query translation and direct verbalization of the corresponding actions in the system. Also, the number of tasks completed correctly was lower in the CTA than in the RTA condition. This might point out that the double workload of verbalizing thoughts and performing actions in the CTA method causes subjects' to make more errors or less easily recover from usability problems experienced in performing a task in the Tool. The cognitive complexity of translating a scenario to a query might affect subjects' task performance

In discussing the type of problems detected per method, it becomes clear that each method revealed unique usability problems. The CTA uncovered more usability issues in general, and more specifically it revealed problems concerning system graphics, navigation, error messages and the layout and organization of the computer screen. The CTA method also seemed to uncover more usability issues of a more cosmetic nature than the RTA method. In comparison, the RTA method uncovered more usability problems related to terminology and meaning of labels, and uncovered more usability issues of a complex nature. Also, its verbal protocols provided more explanatory verbalizations which were considered useful by the software engineers as they provided

information on how to resolve such usability issues in redesign of the NICE Online tool.

Another interesting finding of the RTA method in contrast to the CTA method was the fact that subjects did not verbalize potential problems they had experienced related to statistical, task and query comprehension. Therefore, a slightly positive bias towards the NICE Online tool could be seen in the RTA condition, suggesting that subjects made their comments more positive, thus disguising their 'not so good' result caused by a lack in statistical knowledge, or their possible incomprehension of the task to be performed. The subjects involved in this study were clinicians. A reason for this 'disguising behaviour' might be found in that a 'hospital culture' could exist which prevents them to comment on errors made following their lack in knowledge on for example clinical statistics [10]. However, if the RTA subjects indeed did not express their experienced difficulties and their need for more computer support in certain phases of task execution, then the results of the usability study may be less valid, and could for example lead to missing important insights into additional functionalities required in a system redesign. For example, NICE online is specifically designed to provide its users the opportunity of analyzing ICU data, also from a statistical point of view. While subjects in the CTA condition expressed their need for additional support in statistical reasoning to adequately make use of the Tool in the CTA condition, this requirement was not expressed by subjects in the RTA condition. Based on the verbalizations of the subjects in the CTA condition, the conclusion was drawn to provide additional functionality in the help and information support of the NICE Online Tool.

Our study not only showed that the cognitive difficulty of tasks influenced the total completion time, but also that subjects' task performance in terms of correct tasks was lower in the CTA condition than in the RTA condition. In this case, subjects were not supported by the Tool in adequately performing the task of translating a clinical question to a query, mainly because of the many usability problems that they surfaced. However, for NICE Online, not all of these usability problems might prove to be of importance in redesigning the cognitive model of clinical querying.

Conclusion

Overall, the conclusion can be drawn that the RTA method provided more useful information for the Tool's redesign, because of the more explanatory nature of the verbal protocols, and the provided insight into complex usability issues, Subjects had more time to articulate why they were having problems and they did not focus on the irritations caused by the experienced usability problems in performing their tasks. While the CTA method provided a useful overview of a large number of usability problems experienced including minor usability issues, some of its resulting verbalizations did not provide enough detail to support the Tool's redesign. Also, it is not clear if all these problems in redesign need to be coped with. However, these results also indicate that the RTA method might lead to missing input on additional functionalities in system redesign, because statements concerning physicians lack in task and statistical comprehension were nor adequately made. Though CTA has as its benefit that its subject testing takes less time than RTA, it is of importance to decide which method best to apply in revealing the usability issues that provide enough insight needed for a system's redesign. In light of these formative results, the Physician Data Query Tool is currently under redesign. A future study will focus on a comparison of these two methods in a pre-post design in usability testing of the redesigned Tool.

Acknowledgments

The authors would like to thank the NICE Foundation for making this study possible. Also all NICE participants who acted as subjects in this study are thanked for their contribution. Last but not least, thanks goes out to the head software engineer of NICE Online for his continuous support in conducting this study.

Abstract

A Brain Computer Interface (BCI) provides direct communication from the brain to a computer or electronic device. In order for BCIs to become practical assistive devices it is necessary to develop robust systems, which can be used outside of the laboratory. This paper appraises the technical challenges, and outlines the design of an intuitive user interface, which can be used for smart device control and entertainment applications, of specific interest to users. We adopted a user-centred approach, surveying two groups of participants: fifteen volunteers who could use BCI as an additional technology and six users with complex communication and assistive technology needs. Interaction is based on a four way choice, parsing a hierarchical menu structure which allows selection of room location and then device (e.g. light, television) within a smart home. The interface promotes ease of use which aim to improve the BCI communication rate.

Introduction

Communication and control of the environment is vital to everyday life. In many cases disabled people have gone to extraordinary lengths to communicate. Consider the memoir of Jean-Dominique Baub (Diving Bell and the Butterfly; Le scaphandre et le papillon [1]), which depicts Bauby's life after suffering a massive stroke that left him with amyotrophic lateral sclerosis (ALS) or 'locked-in syndrome'. Bauby developed a system of communication with his speech therapist by blinking his left eye as she read a list of letters to spell out the text and completed his book. Scott Mackler, a neuroscientist in the Veterans Administration Medical Center, also succumbed to ALS and is completely paralyzed, retaining only eye movements. He now communicates through a Brain Computer Interface (BCI), which has led public awareness of the technology (CBS news 60 minutes documentary [2]).

In 2002, Wolpaw et al. [4] offered the following vision: "BCI systems could eventually provide an important new communication and control option for those with motor disabilities and might also give those without disabilities a supplementary control channel or a control channel useful in special circumstances". Allison updated on the prospects of BCI in a 2007 review [5], stating: "BCI systems have just begun to provide significant assistive communication technology to people without other effective means of communication in their home environments." BCI could also be applied in applications where existing communication is desirable, e.g. noisy industrial applications, or as a gaming or entertainment interface [3].

A BCI provides communication from the brain to a computer or electronic device. Communication is achieved by collecting the subject's brain waves, known as the electroencephalogram (EEG), and then translating some information contained within these signals. Currently the information that can be obtained from the EEG is quite limited, as the EEG is inherently noisy containing endogenous and exogenous components, relating to sensory, motor and cognitive activity in the brain. Certain motor and sensory EEG components may be induced or enhanced, revealing the person's intentions when performing some activity, for example moving a cursor on a monitor, in order to control an application. This is potentially powerful when combined with interaction and control of a smart environment [6].

There are three main paradigms: the 'odd ball' paradigm to elicit an event related response (known as the P300 response) from the EEG; an 'imagined' movement paradigm; and the steady state visual evoked potential (SSVEP),. The P300 is a positive exogenous potential which occurs approximately 300mec after a 'rare' or unexpected auditory, visual or somatosensory stimulus and can be used to infer a subject's attention to the stimulus. It requires the average of a number of stimuli to enhance the signal to noise ratio. A component in the motor area of the brain (known as event related synchronization or mu rhythm) can be used to determine if the person is 'imagining' that they are moving, for example, their left or

right hand. SSVEP requires an external visual stimulus to evoke a steady oscillatory component in the EEG, at the same dominant frequency as the stimulus. It is primarily located at the occipital region of the brain. A summary description of these paradigms and possible disadvantages are listed in Table 1. In each case the EEG must be analysed to produce distinct classifications which can be used to navigate an interface, and hence potentially interact with the environment. Misclassification of EEG, of course, results in errors in interface control.

Table 1- Comparison of BCI paradigms

BCI paradigm	**Description**	**Disadvantages**
P300	Stimulus: The Bremen 'speller' uses 6 flashing rows and 6 flashing columns to cover the alphabet and numbers. A number of repeat flashes are performed for the rows and the columns. The evoked potentials are extracted from the EEG for the rows and the columns. Then the classifier uses the row and column to determine the value.	It requires concentration by the user on the screen. The user may become distracted or focus on a wrong symbol/tile. Approximately 16 repetitions are needed to determine the class, due to the small signal to noise ratio. Over familiarization can lower the P300 response.
Imagery	No Stimulus: Imaging the movement of: right hand, left hand, right foot, left foot enhances motor potentials in the brain. Many researchers consider this the 'purest' BCI as there is no external input required	Imagery requires significant training of the user. It also requires concentration. The user has to relate a certain imagined movement to a particular decision. They could easily make a mistake in this process.
SSVEP	Stimulus: A tile or symbol flashes at a defined rate (8-50Hz). Decisions are dependent on the number of stimulating frequencies being used. (Usually between 4 and 10).	It requires concentration by the user as they need to look at the correct flashing tile. It is tiring and suffer5s from possible habituation effects.

The recording of these components for use in a BCI has many challenges. An individual may be better suited to one of these approaches or may be completely BCI illiterate. The recording parameters (electrode location, spatial filters) also need to be 'personalised' to the individual and may be affected by ambient conditions, environment, habituation and fatigue. For people with complex problems the situation is obviously more difficult due to brain injury, additional movement artefacts and reduced periods of concentration. However already, spelling devices can be used to enable those without means of communication to 'voice' their thoughts, by linking to a speech synthesizer.

BCIs are difficult to set up. For example recording constrains the user to be close to an amplifier, requires different approaches, and lacks recognised standards. Placing electrodes on the scalp can be arduous and unpleasant to the user, and requires expertise by an assistant. The equipment comprising electrodes, cap, amplifier, computer and stimulus device is expensive and is not aesthetically appealing. Furthermore, solutions hitherto have been geared towards technical demonstrations to showcase scientific advances without specifically focusing on the needs of the users. However for inclusion in society, a BCI could have a major impact, particularly for those with severe physical disabilities. For the small number with ALS, it may be the only technology that could achieve this.

BCIs with Rapid Automated Interfaces for Nonexperts (BRAIN, [7]) funded by the European Commission's Framework 7 programme, addresses the accessibility of BCIs. In order for BCIs to become practical assistive devices it is necessary to take BCIs into the community. In particular; to make BCIs accessible to a non technical user and their care giver and to ensure that operation is sufficiently robust so that constant intervention is not a requirement. By doing this the BRAIN project intends to make the performance of day to day activities accessible to users for whom this has not previously been the case, thereby promoting the social inclusion of those most in need.

In this paper, we report on the design of generic interfaces [8, 9] for the user, built upon an architecture that will allow a wider variety of applications to be supported. Two threads of development exist. The first is the interface that the user sees and interacts with. Secondly, there is a range of possible applications that could be included and will need to be handled within the same BCI system. For example, enabling BCI control of the television, a music player, a speller; or control over assistive devices within a smart environment.

This is an example of pervasive computing, an emerging research area where sensors and computers support people in their home environments. In these environments, it is highly desirable that the systems and services must be able to adapt and react without the need for people to intervene to configure them.

Methods

BCIs have benefited from improved sensors, smaller amplifiers, better signal processing techniques and a move towards standardization of interfaces. However, it is important that research is focused upon applications that the potential user groups actually want, so the design methodology is to allow users to influence the development. There are two groups: users with complex communication needs and users who may use a BCI as technology of choice for work or entertainment.

User Surveys

BRAIN has adopted a user-centred design approach, involving 2 separate groups of participants in two countries. The user study comprised quantitative and qualitative techniques. In Northern Ireland (United Kingdom), the Cedar Foundation convened workshops and surveyed the needs of six tenants of sheltered smart housing. They expressed an appreciation of the value of the BCI system and a sense of satisfaction of being involved in the development process. One participant was unsure if they would use the technology, but the others were keen to try it. A total of fifteen people participated in the user sessions at a Telefonica site in Spain. The qualitative research was conducted by focus groups, of 8 and 7 participants each and the quantitative part was gathered from surveys delivered to users. The results of the user survey (see below) influenced the design of the user interface, and the target applications.

Interfaces

Interface design is key to uptake of technology, and this is particularly important for BCI, which suffers from a slow communication bit rate. There are three interfaces: (1) An electrical interface via electrodes and amplifiers, which collects EEG from the user; (2) A Graphical User Interface (GUI) which provides feedback to the user regarding the state of the application; and (3) An Application Interface, which provides actuation from the computer to the environment. It is important that a number of applications can be controlled and thus we aim to produce a Universal Application Interface (UAI). The BCI comprises software for paradigm control, signal processing and feature extraction (called BCI2000, Schalk [10]), GUI and UAI, with drivers appropriate to different domotic devices. The user views a GUI and dependent upon the paradigm (SSVEP, P300 but not imagined movement) will view stimuli, presented via external light emitting diodes (LEDs) or on a computer screen.

A number of BCI user interfaces have been reported. These include: the 'Hex-o-Spell' mental typewriter [11], BCI2000 implementations [10], an SSVEP speller [12] and Milan's Adaptive Brain Interface [13]. The current GUI is influenced by the SSVEP work of Piccini [14], and has been adapted to higher frequency LED stimulation [15]. The GUI consists of two modules:

- Display Requirements Module, which adapts the graphical interface to limitations, imposed by the BCI protocol and user preferences.
- Device Interface, which handles the interface between the GUI and the BCI2000-based BCI system.

The BCI system performs signal acquisition and processing, resulting in events that the GUI is able to map to actions of the UAI applications. During operation, BCI2000 stores data, along with event markers and information about system configuration. Additional signal processing routines (written in Matlab) provide classification into four categories (right, left, up, down). Communication between the various modules is by classified user datagram protocol (UDP) packets over a socket connection. The GUI menu structure is defined in extensible markup language (xml), which facilitates the declaration and description of structured classifications. In this manner a menu hierarchy is defined and menu icons associated with appropriate commands. By using xml in this manner the GUI becomes a menu parsing facility. This makes it possible to harness the interface for many different purposes or to facilitate the tailoring of the interface according to individual user needs. The GUI provides the user with navigation through various locations in the smart home. In Figure 1, the menu indicates current location as the "back garden". The down arrow can then select 'controllable' smart devices in this location.

Figure 1- IGUI showing high level location menu within the Smart home

If for example, a room was selected then devices within the room that the user could operate become available. For example, Figure 2 shows the current state of the door. This 'device' can be toggled by selecting 'down', i.e. if the door is currently 'open', it will be closed by actuators associated with UAI.

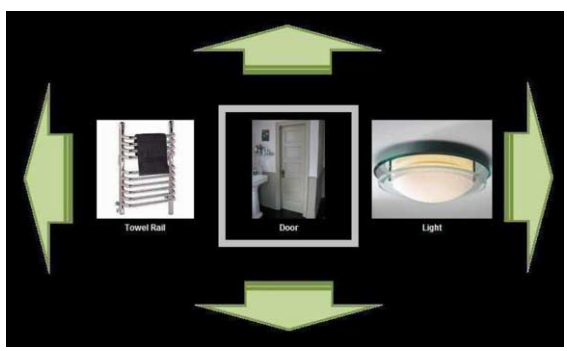

Figure 2-IGUI showing activation of the door open/close (within a room/location)

Results

From the CEDAR workshop and the questionnaire, user requirements were obtained. In terms of physical requirements, all CEDAR participants are wheelchair users with a range of seating postures and positions. It is important therefore to establish the acceptable working distance of the individual when wearing the BCI cap, in relation to device that will house the system. All participants required significant assistance from

care staff for activities of daily living. For BCI, assistance will be required to fit the cap and electrodes. A practical requirement is the importance of training and support, for participants.

In terms of user preferences, communication is the prime function users wish to try, although using the system to support phone calls was not well received. Accessing multimedia content is of interest. Television is the most important entertainment device to participants, and integration of the BCI software into the television or vice versa may support access and usage.

From the Telefonica workshops and questionnaire (N=15; 10 male; 5 female, 21-52 years old) further user requirements were obtained which pertain more towards BCI as an additional technology. Time spent at home was dominated by watching television (TV: 3 hours, Internet: 2.5 hours; work/study: 2 hours; phone communication 2 hours; housework: 1 hour; other: 1 hour).

Requirements for Automation Control: (Video:13 users/ 15; Heating:13; Audio:12; Security:5; Doors:3; Lights:2;). The main concerns of automation systems within the home environment included high prices, the early stage of the technology, reliability and maintenance, security and the new infrastructures (i.e. need for wiring).

Requirements for Multimedia devices (TV:15 users / 15; PC:15; Mobile Phone : 15; DVD: 11; Tuner:6; others:3). The users expressed desire for an entertainment system which can manage multimedia formats, and whose content can be stored in any media server in the home network. Interoperable systems are desired. The system should support the control of many devices, from media players and servers, to domotic devices/sensors, and communication devices, all coming from different technologies. In case of people who need special care, this is considered essential. The television is one of the most valued devices to be controlled by BCI system. The context environmental information should be taken into account to handle smart services.

The BCI system is considered by users as a possible 'remote control' to access to home applications. For a skilled BCI user, this could be a simple task. Techniques to make training easy are requested. The majority remarked that improvements of graphical interfaces are needed to make them more usable. This work has influenced the design of the Graphical User Interface (GUI). The GUI should be implemented on a multimedia workstation which could also function as a television and communication device.

Software and Hardware Testing

Testing has been carried out to ensure that the GUI can interact with the BCI recording system and the domotic applications. Extensive unit testing of menu operation and the ability to issue a command has been completed. Integration testing of the GUI has been successful concerning:

- Demonstration of the correct traversal of the GUI menu via mouse operation. This offers a good test environment and provides the facility for a care giver to operate the GUI should the user require additional assistance. For instance GUI shut down, should the user become tired.
- Demonstration that the GUI will successfully receive and unpack BCI2000 generated, UDP Package content, thereby providing the user with a mechanism to traverse the GUI menu structure via BCI.
- Demonstration that the GUI can issue commands to the UAI which are received and invoked. Commands are invoked as a web service offering the potential for remote control where necessary.

A television (TV) control application has been completed, which allows the user to control the most used functions of a TV set: power on/off, change channel, change volume. A TV set that natively supports the required universal plug and play (UPnP) functionality does not exist in the market place. Most Digital Living Network Alliance (DLNA) compliant TVs are limited to browsing and playing the content found in the Media Servers connected to the home network. However, set top boxes exist that provide remote control features through the ethernet port, e.g. Dreambox 7025 TV tuner (https://www.dream-multimedia-tv.de/en/dm-7025), which allows streaming, electronic program guide retrieval, and schedule of recordings. When the TV input is connected to the Dreambox, the channel displayed and the volume can be controlled from the UAI. A UPnP light emulator was implemented for integration testing. Initial supported devices include UPnP PowerSwitch service and wireless X10 controller. New devices are supported by means of a UPnP wrapper around the native application programming interface (API) of the device.

Initial testing with subjects indicates that the high frequency SSVEP paradigm is feasible in the research laboratory. However, it is necessary to calibrate frequencies for each subject under test and work is underway on a software wizard to facilitate and expedite this process. At present, interface metrics regarding usability in the two target groups still have to be collected.

Discussion and Conclusions

The User Interface uses a 4 way interaction: left, right, up, down. Currently menu items are grouped by space and function in order to ease identification and selection. These groupings can be adjusted within the xml declaration in order to balance depth and breadth of navigation, to facilitate the accessibility of final commands by reducing the number of menu navigation steps required to reach them. Primary grouping is made by the rooms associated with the users' housing environment: living room, bedroom, hall etc. and then by function: lighting, television, heating. An additional classification of menu item 'Sticky' is used to ensure that significant applications such as a Speller, or the ability to answer the door or phone are always available. The environment to deploy UAI applications as web services has been set up under the Equinox OSGi framework. UAI applications are implemented as OSGi bundles that are easily installed in the system. The UAI is able to filter the discovered UPnP devices so that only authorized devices are operated. The software light emulator and

light control application has been successfully tested, and indicate the potential for more complex domotic device interaction. Additional user trials will allow us to collect information which can then be used to impart intelligence into the menu structure. This can improve the effective bit rate of the BCI.

The Graphical User Interface is intuitive and can be personalized. The menu is based on photographs of the intended location/device, which may be personalized to the specific environment, and so should be intuitive in use. It does not rely on literacy. The size of the menu could be scaled, appropriate to poor visual acuity. The menu structure may be easily extended for further rooms/devices. Each device can have additional menus appropriate to the complexity of operation, e.g. a media player will have more controls than a simple switch. Interaction with the UAI is via web services, and a queue of current events. GUI and devices can communicate with this queue to indicate their current state, e.g. turn a light off, if already on. Communication with the BCI is via UDP network packets. This provides a decoupling of technologies, enabling independent development (e.g. BCI200 has been developed in C++, whereas the IGUI has been developed in JAVA). This provides an IGUI which is potentially open to the wider community for enhancement.

In conclusion, we are in the process of implementing a BCI system designed to be used in the community. Paradoxically initial testing has occurred in a controlled setting, and hence our overall rationale still requires validation. However, we believe that the approach allows us to deploy a system to deliver a number of services, which the users desire, with familiar control using a consistent extendable (and in the future) context aware intelligent GUI. These advances are necessary for BCI to become practical assistive devices, but are not sufficient, and we need further progress in electrodes, caps, signal processing, convenient set-up and detailed understanding of user interaction with the system.

Abstract

Clinical guidelines (GL) play an important role in medical practice: the one of optimizing the quality of patient care on the basis of the best and most recent evidence based medicine. In order to achieve this goal, the interaction between different actors, who cooperate in the execution of the same GL, is a crucial issue. As a matter of fact, in many cases (e.g. in chronic disease treatment) the GL execution requires that patient treatment is not performed/completed in the hospital, but is continued in different contexts (e.g. at home, or in the general practitioner's ambulatory), under the responsibility of different actors. In this situation, the correct interaction and communication between the actors themselves is critical for the quality of care, and human resources coordination is a key issue to be addressed by the managers of the involved healthcare service. In this paper we describe how computerized GL management can be extended in order to support such needs, and we illustrate our approach by means of a practical case study.

Keywords:
Clinical guidelines, Human interaction and communication, Human resources coordination.

Introduction

Clinical guidelines (GLs) are defined as "systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances" [1]. GLs exploitation is meant to improve the quality and to reduce the cost of healthcare, putting evidence based medicine into practice, and is progressively spreading in several countries. As a matter of fact, a lot of national and international institutions have recently been engaged in developing and disseminating GLs. Moreover, the medical community has started to recognize that a computer-based management of GLs can further increase GL advantages, providing relevant benefits (e.g. automatic connection to the patient databases, and decision making support) to care providers and patients. Many different systems and projects have been developed to this hand (see e.g. [2-4]).

The goals of these systems are mainly the ones of supporting physicians in patient care by representing and executing a GL. However, it is worth noting that some GLs, mainly dealing with chronic diseases, require that patient treatment is not completely performed in a single location (e.g. the hospital), but is continued in time, often in a life-long perspective, and distributed in *different contexts* (e.g. at home, or in the general practitioner's ambulatory), under the responsibility of *different actors*. In this situation, the *correct interaction and communication* between the involved actors is critical for the quality of care, and *human resources coordination* is a key issue to be addressed by the managers of the involved healthcare services. None of the available computerized systems for GL management explicitly addresses these needs, and interaction is nowadays completely demanded to the different actors. Sometimes the responsibility of notification is even demanded to the patient, without a check of communication completeness and correctness. For instance, in Italy, the discharge letter is given to the patient, who has to notify it to her general practitioner.

In this work, we propose an extension of a computerized GL management tool in order to support coordination of multiple actors operating on the same GL. In particular, we first introduce an extension of the GL representation formalism with new dimensions, meant to *color* the GL actions with *context, role* and *competence* information. Then, we describe how human resources coordination and human interaction and communication can be supported through notification and query answering services. The querying facility, in particular, can help both during GL execution and off-line (e.g. before execution, and independently of any specific patient's data). A practical implementation of this work is represented by an extension of the GLARE system, a domain-independent system for GL acquisition and execution [5], that we are developing since 1997. Resorting to the GLARE formalism, we will illustrate the application of our approach to the "Management of harmful drinking and alcohol dependence in primary care" GL developed by the Scottish Intercollegiate Guidelines Network (SIGN) [6], which we have adapted to the Italian context. However, although we have implemented our approach in GLARE, it is worth stressing that the methodology we propose is completely general and application-independent.

The paper is structured as follows: in the next section we describe the extension to the basic GL representation formalism required by our approach, as well as the notification and the query answering service. In the Results section, we exemplify a practical application of our approach considering the alcohol-related disorders treatment GL. Finally in the last section we address some concluding remarks.

Materials and Methods

Colored Guidelines: representation formalism

In the literature, the majority of the GL representation languages share the same basic primitives, from which we will start to describe the extensions we propose in this paper. Obviously this grants for generality: despite the fact that our approach is being integrated with GLARE, all the considerations could be easily adapted to other GL management systems.

In particular, a GL is typically represented by a graph, where nodes are the statements/actions to be executed, and arcs are the control relations linking them. Actions can be *atomic* or *composite*, defined in terms of their atomic components via the has-part relation. Three main types of atomic actions can then be identified[1]: *work actions,* which describe a procedure which must be executed at a given point of the GL; *query actions*, which represent requests of patient data; *decision actions,* which embody the decisional criteria that can be used to select among alternative paths in a GL. *Control* relations establish which actions can be executed next, and in what order: *sequence, parallelism*, *alternative*, and *repetition* constructs are typically available. In some systems (e.g. in GLARE) temporal constraints, such as the delay between two actions in sequence, can also be provided. Such notions will be used in the examples in the Results section.

In order to deal with human interaction and human resources management, we propose to extend the semantics of each action by *coloring* it with three new dimensions:

- **context:** it specifies where the action can be executed (e.g. in-patient care, community medicine). Observe that a context is not necessarily a physical place, but it is an operative environment. For instance, community medicine can refer to the patient's home or to the general practitioner's ambulatory;
- **role:** it specifies who can execute the action (e.g. physician, nurse);
- **competence:** it specifies that the action can be executed only by actors with some specific abilities (e.g. pharmacological treatment of abstinence syndrome).

It is worth noticing that not all combinations of values of the three parameters are usually possible. Moreover different actors may share the very same competence. However a competence may assume different meanings according to the role.

[1] In the following, without loss of generality, we will use the GLARE system terminology for action names.

At design time, the specification of a list of possible contexts and of a list of possible roles is mandatory for every action in the *colored* GL; on the other hand the competence dimension specification is not always required. In the case that the competence list is empty, no specific restriction needs to be applied; otherwise, only the actors having the required competences will be allowed to execute the action at hand. Moreover, all dimensions are represented by a list of values, but the interpretation of such lists is different. Context values must be interpreted as alternative ones: in the case that two or more contexts are specified, it means that the action can be executed in any one of the contexts. The same consideration holds for role values: if two or more roles are provided, the action can be executed by any one of the actors. On the other hand, the competence values must be interpreted in conjunction: if two or more competences are specified, the actor responsible for performing the action at hand will need all the abilities.

Example. The action "Brief intervention for hazardous and harmful drinking" (see action 11 in Figure 1, Results section) in the alcohol-related disorders treatment GL [6] is color as follows:

- *context: community medicine, SERT medicine (i.e. an Italian service similar to the Mental Health Service in U.S.A.), in-patient care, hospital care ambulatory;*
- *role: physician, nurse;*
- *competence: psychological support.*

Notification service

As observed in the Introduction, in many real world situations no automatic notification exists to the different actors involved in the execution of a GL on a chronic patient. The issue is particularly critical when an action is followed by another action to be executed in a different context, like, e.g. when a patient is discharged from a hospital, and must be cared by her general practitioner. The absence of an automatic notification exposes the patient to the risk of being "left alone", without any healthcare operator who is formally in charge of her monitoring or treatment procedures; especially when dealing with pathological conditions involving low compliance patients (like e.g. alcohol-addicted ones), it is not really acceptable that the notification to the new responsible actor is up to the patient herself.

Our approach allows to properly deal with this issue, since each action is *colored* with information about context, roles and competences required for its execution. In particular, we have implemented a notification service, which is automatically activated at execution time. By means of this service, as soon as a GL action is completed, all the contexts, roles and competences *coloring* the next action to be executed are collected, and a notification is sent to the proper person or service manager. In this way, the patient is constantly under the responsibility of a proper healthcare operator, and communication with the responsible is always possible for the other people involved in the GL execution.

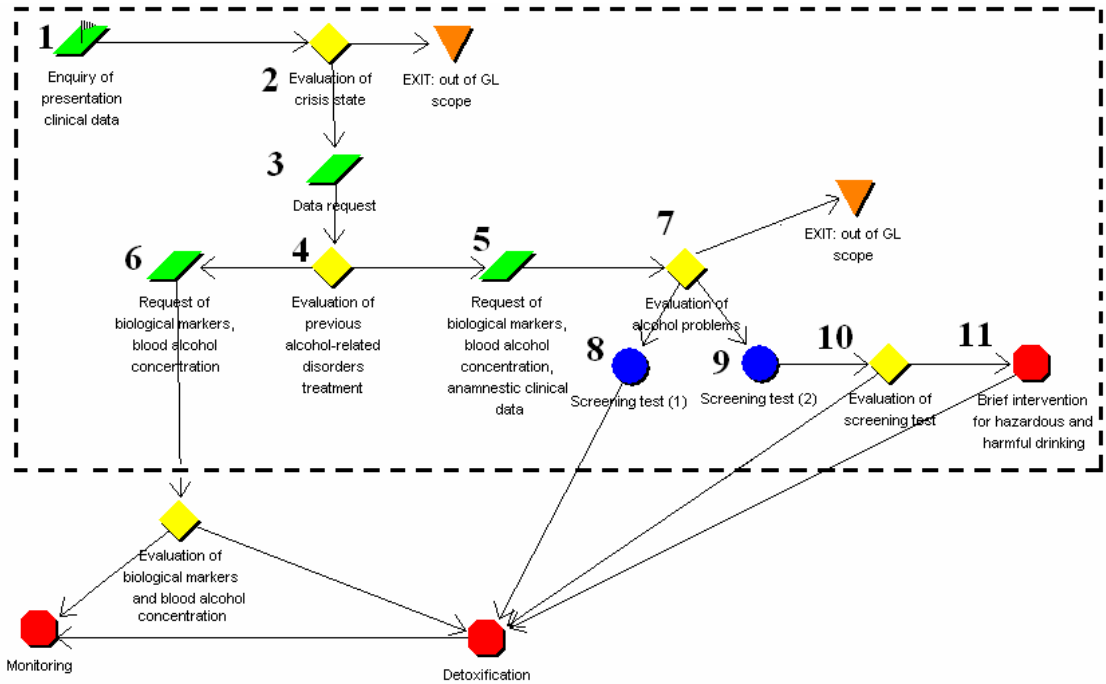

Figure 1 - Part of the alcohol-related disorders treatment GL acquired in GLARE

An example of the notification service use will be provided in the Results section.

Query answering service

In addition to the notification service, we have also defined a query answering service, which may help both individual actors involved in the GL and healthcare service managers.

An individual actor (e.g. a physician, a nurse) represents one instantiation of the three dimensions used to *color* a GL: she works in a context, covers a specific role, and has (or can have) a set of competences (actually the instantiation may be partial, since specific competences may be absent).

By means of our approach, given her "*colors*" the actor is allowed to issue some queries, with the aims of:

- focusing on **what** actions she will **necessarily/potentially** be asked to be responsible of; this type of query can be issued both during GL execution, referring to future actions, or off-line, considering the overall set of actions composing the GL;
- scheduling **when** she will **necessarily/potentially** be involved in the GL execution, and referring to what actions; this kind of query will obviously be issued at execution time;
- discovering **with whom** she will **necessarily/potentially** be involved, i.e. who are the actors responsible for the actions to be executed before/after the ones she is in charge of. This type of query, which can be useful both at execution time and off-line, strongly facilitates interaction and communication.

On the other hand, healthcare service managers (like e.g. hospital administrators, or social services directors) may be interested in issuing queries with the aim of:

- verifying **what human resources** are **necessarily/potentially** involved in a GL execution, and **when**; this type of query, which is useful off-line, allows the manager to properly coordinate and allocate human resources themselves. The information about the list of people covering the same role or having the same competences helps the manager to optimize human resource allocation also when people in the context she manages are involved in different distributed GLs at the same time.

Note that temporal queries are answered resorting to advanced AI techniques integrated in GLARE [7]. Examples of the different query types will be provided in the Results section.

Results

As an example, we present an application of our approach to a GL for alcohol-related problems [6], adapted to the Italian context. We have acquired and *colored* such GL in GLARE. The possible values of the three dimensions used to *color* all GL actions are the following:

- context: Community medicine (C1), SERT medicine (C2), in-patient care (C3), hospital ambulatory care (C4), social services (C5), social voluntary work (C6), family (C7);
- role: physician (R1), nurse (R2), healthcare assistant (R3), social assistant (R4), social worker (R5), patient (R6), relative (R7);
- competence: pharmacological treatment of abstinence syndrome (CO1), psychological support (CO2), family and group approach (CO3).

For the sake of brevity, we will focus on a subpart of the GL, shown in the dashed box in Figure 1. The GL starts with a request of some clinical data (query action 1), used in the following decision action (decision action 2), which is meant to diagnose if the patient is currently experiencing a crisis state. Alcohol-related crisis is outside the GL scope. If, on the other hand, the patient is not experiencing a crisis, her history is collected (query action 3), in order to distinguish whether it is the first time that the patient is in treatment for alcohol-related problems, or not (decision action 4). New patients require the collection of biological markers, blood alcohol concentration and anamnestic data (data request 5), while anamnestic data collection is not needed for patients who were already cared for alcohol related disorders (data request 6). Focusing on new patients, a diagnosis about alcohol-dependence is performed (decision action 7), on the basis of the collected information. In the case that the patient does not show alcohol-dependence, the GL execution is ended. Otherwise, two different treatments can be applied, on the basis of the severity of alcohol-dependence; both start with a screening test (work actions 8 and 9 respectively). Focusing on patients who show a mild alcohol-dependence (work action 9), evaluating the screening test results (decision action 10), the patient can be selected for the brief intervention for hazardous and harmful drinking (composite action 11), which basically consists in a set of motivational interviews. Actions 1 to 11 in Figure 1 are *colored* as described in Table 1.

We now provide an example of the notification service use. Suppose that, during a specific GL execution on a new patient X, the "Evaluation of previous alcohol-related disorders treatment" action (action 4) is performed by actor Y, being Y a social assistant (R4), who is employed in social services S (C5). Being X a new patient, action "Request of biological markers, blood alcohol concentration, anamnestic clinical data" (action 5) will be scheduled for execution next. All the possible responsibles for action 5 (i.e. all physicians (R1) in contexts C1-C4) are notified by the GLARE facility about the fact that one of them should take care of the patient for the needed data collection. If temporal constraints about the action execution are specified in the GL (e.g. if data collection must start as soon as possible, for instance within one day from the completion of action 4) such constraints are provided in the notification message as well. As a matter of fact, they can be of help for the potential actors in scheduling their commitments.

Table 1 – GL actions in dashed box of Figure 1 and their "colors".

Action number	Action description	Context	Role	Competence
1	Enquiry of presentation clinical data	C1, C2, C3, C4, C5	R1, R2, R4	-
2	Evaluation of crisis state	C1, C2, C3, C4, C5	R1, R2, R4	-
3	Data Request	C1, C2, C3, C4, C5	R1, R2	-
4	Evaluation of previous alcohol-related disorders treatment	C1, C2, C3, C4, C5	R1, R2	-
5	Request of biological markers, blood alcohol concentration, anamnestic clinical data	C1, C2, C3, C4	R1	-
6	Request of biological markers, blood alcohol concentration	C1, C2, C3, C4	R1	-
7	Evaluation of alcohol problems	C1, C2, C3, C4	R1	-
8	Screening test (1)	C1, C2, C3, C4	R1, R2	-
9	Screening test (2)	C1, C2, C3, C4	R1, R2	-
10	Evaluation of screening test	C1, C2, C3, C4	R1, R2	-
11	Brief intervention for hazardous and harmful drinking	C1, C2, C3, C4	R1, R2	CO2

Observe that the patient is free to choose among different contexts for being visited and for taking her lab exams, as requested by action 5: she can go to the hospital (C3 and C4), as well as to the general practitioner (C1), or to the SERT centre (C2). The added value of our facility is that all contexts know that the patient is meant to contact one of them; as soon as one context is chosen by the patient, one physician employed there will explicitly accept the responsibility of action 5, and all her

colleagues in the same as well as in the other contexts will be automatically contacted and properly informed by GLARE. It is also worth noting that, if the patient does not contact any context, the notification service can work as a reminder for all potential responsibles. In this way, one of them will then proactively contact the patient, and finally accept the responsibility of action 5.

A set of queries, of the types introduced in the previous section, are now provided as an example of the query answering service use.

Query1: social assistant *Y* (R4) asks off-line **what** actions she will **necessarily/potentially** be required to be responsible of in the alcohol-related GL.

Answer1: she will be potentially involved in the following actions: "Enquiry of presentation clinical data" (action 1), "Evaluation of crisis state" (action 2).

Query2: during a specific GL execution, social assistant *Y* (R4), who has determined that the treatment path will start with "Request of biological markers, blood alcohol concentration, anamnestic clinical data" (action 5) asks for information on the actions to be executed next, in order to verify **with whom** she will **necessarily/potentially** be involved.

Answer2: "Evaluation of alcohol problems" (action 7) is the next, mandatory action to be executed, and can be performed by a physician (R1), in any of the contexts C1, C2, C3 and C4. Depending on the evaluation results, "Screening test (1)" or "Screening test (2)" (action 8 and 9) which are mutually exclusive, will be executed next. Both can be performed by a physician (R1) or by a nurse (R2) in C1, C2, C3, or C4 contexts.

Query3: the responsible of a hospital ambulatory care (C4) asks for information concerning the execution of the "Brief intervention for hazardous and harmful drinking" (action 11) in order to discover what **human resources** are **necessarily/potentially** involved in its execution (take from the GL colors), and **when** (inferred by temporal reasoning [7] on the constrains in the GL).

Answer3: The action is not mandatory during the GL execution, it has a minimum duration of 1 day and a maximum duration of 3 days, and in the case that it will be performed, its execution will be done by a physician (R1), who has the competence of alcohol-related disorders management (CO1), within the 9th day from GL start.

Conclusion

In this paper we have presented an extension of the basic computerized GL management support, meant to deal with human interaction and communication. Such extension is strongly needed when dealing with distributed GLs, which ask for a continuous patient monitoring and treatment, operated in different contexts, under the responsibilities of actors covering different roles and having different competences.

To the best of our knowledge, the existing GL management systems have not explicitly considered this issue yet. It is just worth noting that Fox's group has recently proposed an extension of the PROforma representation formalism [8] in order to specify who will execute an action. However their goal is not the one of managing actor interactions in different contexts: they exploit actor information for better contextualizing GLs taking into account local human resources, and for flexibly adjusting them through delegation.

Our approach is currently integrated in the GLARE system - even though it is general enough to be easily transferred to other GL management systems as well. In the future, we will complete the implementation, and add further facilities. First, we will structure the available contexts, roles and competences information in a hierarchical fashion, by acquiring the needed knowledge from domain experts. This will allow us to better structure the *color* information in the GL actions. Moreover, we have implemented a user-friendly graphical interface, in order to allow the different actors involved in a distributed GL execution to easily and quickly obtain the answers to their typical queries, and to properly deal with communication and resources coordination needs.

LuMiR: The region-wide EHR-S in Basilicata

Mariangela Contenti, Gregorio Mercurio, Fabrizio L. Ricci, Luca D. Serbanati

National Research Council, Institute for Biomedical Technology, Italy

Abstract

The Lucania – Medici in Rete (LuMiR) project aims to support the shift from organization-centric to patient-centric healthcare in Basilicata, a region in the southern Italy. Main objective of the project is to foster collaborative, multidisciplinary and cross-organizational healthcare processes by developing and stimulating the adoption of a region-wide, software infrastructure, the LuMiR system,. It is a suite of e-services that facilitates the sharing of patient related clinical data among authorized professionals, by enabling the interoperability among Electronic Medical. In the paper the LuMiR project approach is discussed, pointing out the methodology adopted in the design and development of the LuMiR system, the peculiarities of the system architecture and interventions scheduled to mitigate the risks related to the large scale adoption of the LuMiR system itself.

Keywords:

Electronic health record system, Service oriented architecture.

Introduction

Recent trends in healthcare service delivery promote integrated and patient-centric care, i.e. the continuity and coordination of care, provided by multidisciplinary teams, along the continuum of a disease, and across multiple points of care (e.g. [1]). In these complex processes the timely availability of patient related medical information assists professionals in recomposing the fragmented activities, taking more informed decision, delivering more appropriate care and preventing medical errors. In this perspective the systematic adoption of Healthcare Information Technologies (HITs) is a promising opportunity to innovate the healthcare sector, to protect the economic sustainability of healthcare services and to improve their quality. The LuMiR project[1] intends to support the shift from organisation-centric to patient-centric models of service delivery in Basilicata, by promoting collaborative, multidisciplinary and cross-organizational healthcare delivery processes and supporting them with a software infrastructure that provides services for sharing patient related clinical data among authorized healthcare professionals.

[1] The Lucania – Medici in Rete (LuMiR) project is jointly carried out by the Institute of Biomedical Technologies of the Italian National Council of Research and the Basilicata Region (website (in italian): www.sanitaelettronica.cnr.it/lumir).

Our format introduces the Italian e-Health institutional initiatives which frame the LuMiR project, followed by describing the Basilicata region, its healthcare system, and the heterogeneous environment in which the LuMiR system is to be deployed. The next section describes how the LuMiR approach is presented together with its incremental three-phased life cycle. Architectural details on the LuMiR system are then provided, and additional details on the ongoing implementation activities conclude the paper.

eHealth Institutional Initiatives in Italy

The planning and programming of strategies to innovate the healtcare sector (e.g. [2]) has well as their carrying out has been keeping busy many industrialized countries all over the world. e-Health applications are pervading both the back-office and the front-office of the healthcare delivery systems. At the heart of many complex platforms there is the Electronic Health Records System (EHR-S) [3], a system for recording, retrieving and manipulating information in electronic health records. Such an EHR-S serves a variable set of interdependent clinical, relational, administrative, and managerial needs, according to the specific implementation goals and business processes to support.

Numerous eHealth programs and projects have been carrying out in Italy. The precursors started by regional or local autonomous initiatives (e.g. [4, 5]). The more recent are following European directives and national roadmaps (as described e.g. in [2]). Actually, since 2005, a national permanent eHealth Board (Tavolo di Sanità Elettronica, hereby TSE), was established to carry out a national strategy for eHealth in order: i) to harmonize the eHealth initiatives individually promoted by each of the 23 federated regional governments; and ii) to support a coordinated implementation of a cross-regional interoperable HIT infrastructure.

To this aim the TSE issued an high level conceptual framework [6], as well as an architectural specification for a software infrastructure for distributed healthcare processes, namely the eHealth Basic Infrastructure (Infrastruttura di Base per la Sanità Elettronica, hereby IBSE) [7].

The LuMiR project is the enactment in Basilicata of the GP's Network Pilot Program (Rete dei Medici di Medicina Generale, hereby RMMG). The RMMG program targets the primary care settings in 9 regions of the central and southern Italy. It was funded by the Ministry of Economy and Finance in 2006 and managed by the Department of Technological Innovation

of the Presidency of the Council of Ministers. It aims to foster the implementation and adoption of interoperable regional software infrastructures in order to stimulate and support the cooperation among general practitioners (GPs) or paediatricians and the other healthcare professionals in the delivery of ICT-enhanced integrated healthcare services.

The Basilicata region and the LuMiR Project

The Basilicata region covers 9,992 km², has a population of 596,546 citizens and a very low population density compared to that of Italy as a whole (in 2001about 61 vs 192)[2]. It is the most mountainous region in the southern Italy with citizens mostly concentrated in the major cities and the hinterland villages under-populated. Transport infrastructures are scarcely developed with railroads nearly completely lacking, and only five important highways serving the street traffic.

The Regional Healthcare System has been recently reorganized in two Provincial Health Authorities (PHAs) (the ASP and the ASM), which are entitled of managing and carrying out the delivery of healthcare services for all the welfare beneficiaries. The PHAs directly manage respectively 3 and 4 hospitals, each of which providing both inpatient and outpatient care, as well as many other smaller clinics for outpatient care disperse in the territories. More in details in the Basilicata region primary care is in charge to a total of 510 general practitioners, 70 paediatricians and 140 points of medical guard. Secondary outpatient care is also provided by 108 among public ambulatories and laboratories as well as many more authorized private ambulatories[3]. Secondary and tertiary care is also provided by the San Carlo Hospital Trust, a public hospital autonomous from the PHAs, and by the Crob Oncology Regional Hospital, a regional institute for research and care.

The healthcare processes supporting the daily services delivery sensibly vary from site to site, reflecting the geographical and demographical peculiarities of each area, as well as the distribution and organization of the local healthcare facilities. Also the diffusion of HITs and the level of automation in the healthcare value chain is heterogeneous, even if many local software vendors operate in the market. The software systems deployed in islands of automation include: (i) a certain number of specialized applications supporting operational and clinical activities in hospital departments and/or ambulatories, each one isolated from the others; (ii) only one fully integrated Hospital Information Systems, and (iii) several different EMR for GPs and paediatricians offices. The more relevant existing systems for the LuMiR project are: a registry of welfare beneficiaries' personal data; a cross-organization booking system for outpatient services; a networked service for the management of first aid/hospital admission, discharge and transfer; a distributed authoring tool for medical reports connected with a centralized repository; and a specialized asynchronous cardiac teleconsulting system. In this heterogeneous environment the LuMiR project targets the design, development, and deployment of the LuMiR system, an interoperable EHR-S which interconnects at application level both software-intensive information systems running in individual points of care (Figure 1) and existing repositories which support specific regional information flows.

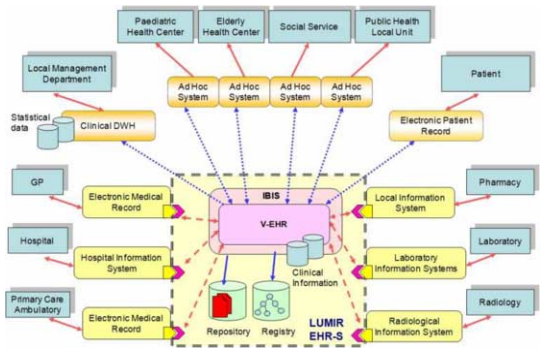

Figure 1- The LuMiR system conceptual architecture

More in general the LuMiR project intends to promote the diffusion of eHealth all over the region, accelerating the modernization process in all the points of care, stimulating the reengineering of business processes and the development of novel services for professionals and citizens. According to the LuMiR project vision, in the long term all the public points of care in the region will be interlinked together via the LuMiR system and all the citizens will be able to freely access the information on their own health status. Other business activities which will indirectly benefit of the LuMiR system are those related with the secondary use of de-identified and aggregated clinical data and information (e.g. management and governance of healthcare organization, epidemiology studies, biomedical and healthcare research, etc.).

The LuMiR System approach

The design of the LuMiR system was influenced by the business requirements described above. It was also constrained by the guidelines issued by the TSE and the technical specification issued by a restricted RMMG harmonisation workgroup, part of which under development at the beginning of the project, and in continuous evolution during the project lifetime. The more relevant principles inspiring the LuMiR system design are: (i) use of multiple views on EHR contents; (ii) promotion of technical and semantic interoperability; (iii) integration of legacy applications; (iv) enforcement of national guidelines and international standards; (v) promotion of reusability; (vi) easy adaptability to changes in the environment; and (vii) assurance of information security and privacy by policy-based configurable models.

Due to the many institutional, organizational and technological issues, the development of the LuMiR system has been based on an incremental life cycle model. In this way a prototype implementing the core functionalities was early available.

[2] 56% of the citizens live in the 12 major cities of the region, 27% live in medium towns (with a population comprised between 5,000 and the 9,999 inhabitants), and the remaining 17% live in the smaller villages which are under-populated.
(Data from the EC DG Regio "Portraits of the region" series http://circa.europa.eu/irc/dsis/regportraits/info/data/en/index.htm)

[3] Data from the Italian Ministry of Health.

It was used to better elicit the LuMiR system requirements with the direct involvement of the end-users following a socio-technical approach. Actually three incremental releases of the LuMiR software infrastructure were scheduled as described in the next section.

The LuMiR system was developed with the aim not only to receive the TSE guidelines and technical specifications, but also to extend them with some additional functionalities, in order to overcome some limitations they present.

The EHR-S is, in the TSE specification, a document-oriented healthcare information system. Actually the core component of IBSE is the Health Individual Broker (InfoBroker Individuale Sanitario, hereby IBIS), which implements an efficient storage of digitally signed clinical documents, by referencing, routing, notifying, retrieving and making them proactively and/or on-demand available to the authorized healthcare providers. This approach is compliant with the Integrating the Healthcare Enterprise initiative's Cross Enterprise Document Sharing profile (IHE-XDS) for cross-organization exchange of patient related clinical documents. In addition, the mandatory requirement that each document circulating in IBIS have to be digitally signed (e.g. by its author) reflects an important business rule in the healthcare domain. Actually it is intended to enforce the legal value of clinical documents (e.g. prescription, referral, certificates) which, in the paper-based daily working practice need to have handwritten signatures. At the same time this approach is coherent with the larger process of paper dematerialization. Nevertheless, it is not completely responding to the end-user need as emerged in the real environments observed in Basilicata. Actually the number of clinical documents related to a single citizen can grow sensibly, especially if a chronicle disease affects him/her. This means that healthcare professionals need value added services through which classify and organize, from a clinical perspective, the huge amount of IBIS contents. Actually if these services are missing the search and collection of a restricted set of meaningful patient related clinical information could reveal not sufficiently efficient and effective. This in turn implies that the overall software system runs the risk to be refused by healthcare professionals. Thus, in order to overcome these limitations, in the LuMiR approach the IBIS specification was extended in two opposite directions:

[1] some additional concepts, i.e. Contact, Episode of Care and Health Issues, were introduced to support different level of classification ;

[2] other additional functionalities were introduced with the objective to refine the course granularity of documents.

In respect of the former intervention, a Contact is a set of Healthcare Services (HCService), each of which provided by an healthcare professional during an encounter with the patient, considered relevant for the patient's healthcare status documentation and described in one or more clinical documents. An Episode of Care is a sequence of correlated and chronologically ordered HCServices associated with a patient Health Issue. These concepts have a quite long tradition in the healthcare literature [8] and also recur in some healthcare standards (e.g. CEN TC/251 EN 13940-1:2006). They offer a mean to classify and organize patient related clinical documents, and can be used to simplify the consultation of a certain patient's IBIS content. In order to support these concepts in the LuMiR system an additional component, namely the LuMiR Infobroker, was introduced. It is described in the next section.

On the other side in order to answer complex and longitudinal user-requests, as for instance in the synthetic grouping or charting of some biological parameters, a set of documents can reveal hard to process. For these kinds of user-request it is preferable to manage smaller chunk of content or atomic structured data and aggregate them according to pre-defined or on-demand forms. In order to cope with this additional requirement, in the LuMiR architecture the Virtual Healthcare Record (VHR) component has been introduced [9]. The description of this component is outside the scope of this paper

Phasing the LuMR system development

In the following LuMiRp0 and LuMiR1 are briefly discussed. LuMiRp0 is an early prototype where large part of the non-functional requirements (e.g. security, privacy and reliability) were neglected. It was rapidly developed in order to be used as a sort of trial environment to carry out a field experiment. It served small groups of selected healthcare professionals, providing them with all the medical information and documents about a restricted set of volunteer patients that where easily collectable, because already archived in digital format in some regional or local healthcare information systems. To this aim the LuMiRp0 system integrates minimal services for sharing and storing patient related clinical data, but introduces to the end-users the key concepts of Contact, Episode of Care and Health Issue described above.

Figure 2 presents a screenshot of the Viewer that physicians operate for browsing patient related medical data. Thanks to the release of the LuMiR p0 prototype, care providers were involved in the project since the early phases, and this made possible to:

- better understand in which situations GPs (paediatricians) and clinicians effectively cooperate together in the care of their patients;
- identify how and in which contexts the LuMiR system could promote a paradigm shift toward integrated care, more centred on communication and collaboration among professionals; simplifying and empowering the daily working practices; and
- identify some measurable quantitative indicators to evaluate the improvement resulting from the new approach to patient care.

LuMiR1 is a distributed, component-based system focused on the interoperability, security, privacy and reliability issues. It is based on a peer-to-peer communication infrastructure and implements a Service Oriented Architecture (SOA). To integrate legacy as well as new client-applications LuMiR1 promotes a standard adapter and various specific drivers that adjust the peculiarities of any of these client-applications at the uniform, standard-based LuMiR1 internal space requisites.

On the server-side the LuMiR1 components include:

Figure 2- Screenshot of the LuMiR p0 system

- the Public Cooperative System software infrastructure (SPCoop);
- the IBIS components for sharing of digitally signed clinical documents;
- the LuMiR Broker which provides high-level services of message dispatching, event notification, document management, and security.

SPCoop is a technical and organizational nationwide large scale e-Government SOA providing network, communication, basic interoperability, application cooperation and security services among jurisdictionally independent public administrations (Domains). IBIS is the document-oriented federated Registry/Repository system in which: *(i)* a federated ebXML-based Registry stores document content metadata; *(ii)* Repositories are storages where electronic documents (pointed at by Registry records) reside and are retrieved by their name or properties; and (iii) Access Gateways (AG) demarcate jurisdictional domains by controlling accesses in/from the domain . According to the TSE recommendations, in the actual implementation of IBIS, the exchanged clinical documents are compliant with the HL7 CDA r2 standard and the ad-hoc restriction defined by the RMMG harmonisation workgroup. Figure 3 depicts the functioning of the LuMiR Infobroker.

From a behavioral point of view, the interaction among the LuMiR1 system, any PoC EMRs (whatever a legacy system or an ad-hoc application), and the IBIS AGs is described in the followings.

During the storage phase:

- The doctor captures with his/her PoC application all the medical information about each encounter with his/her patients. For each encounter he/she, produces one or more correlated HL7-CDA documents, and via an ad-hoc software driver passes them to the LuMiR standard Adapter;
- The standard Adapter encapsulates in an HL7 v3 message the information on the Contact, the Episode of Care and the Health Issue, as well as the HL7-CDA document(s) in attachment, and forwards it to the LuMiR Broker via a dedicated, document-style web-service interface. The standard Adapter is implemented by using messaging-based integration patterns [10];
- The LuMiR Broker processes the received message, extracts the attached document(s), asks to the appropriate AG to store them in appropriate repository and register their metadata in the ebXML Registry. Then the Infobroker stores the information related to Contact, Episode of Care and Health Issue, together with the unique identifiers of the stored documents in the Viewer's repository;
- The LuMiR Broker also notify the information related to Contact, Episode of Care and Health Issue and document(s) metadata to all PoCs who subscribed their interest in receiving the notification ,.

During the retrieval phase

- Healthcare professionals consult the contents of a patient EHR via the Viewer that, apart from technological changes transparent to the end users, looks and behaves as the LuMiRp0 Viewer. More in details the information related to Contacts, Episodes of Care and Health Issues are retrieved from the LuMiR1 Registry, the documents metadata from the IBIS Registry and the documents by the IBIS Repository (Figure 2).

Due to the fact that also the IBIS AG internally contains another Infobroker, this infrastructure actually realizes a two level broker-based architecture in which:

- multiple distributed IBIS AGs, one for each of the SPCoop Domain, interact with each other via the IBIS Infobroker, and
- a centralized LuMiR Infobroker plays the role of an intelligent mediator between PoCs software applications and the IBIS AG infrastructure.

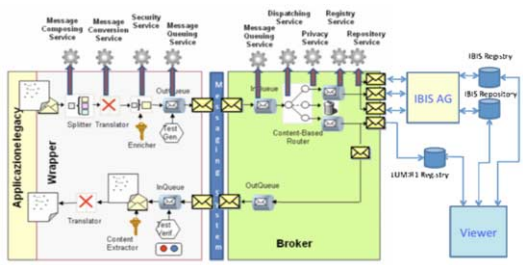

Figure 3-The LuMiR1 InfoBroker

For the system development two different software houses were entrusted of the implementation of different component. Also those software houses providing one of the legacy systems running in the PoCs enrolled in the project, were involved in order to implement software adapters for the integration of their products with the LuMiR system.

Discussion and Conclusion

At the moment the field experiment with LuMiRp0 is concluded in two different public healthcare organizations of the Basilicata Region. The development of the LuMiRp0 and its adoption in the field experiment were burdensome but fundamental activities. On one side, the simplification of the technological aspects facilitated the tasks in charge to the software vendors and allowed a rapid development of the integration adapters. Also the involvement of the software vendors since the early stages of the project has been profitable for the establishment of a collaborative environment and business partnerships, strategic for the subsequent more complex phases of the project. On the other side, the design and development of the LuMiRp0 system, supported with narrative scenarios and focus groups, put the focus on the socio-technical dimensions and the actual business processes, enabling to elicit important system requirements. Also, the set up and execution of the field experiment provided important lessons learned on possible hindrances for the final adoption.

The LuMiR1 system is released this summer, and the field experiences brought us to define a specific roadmap for the large scale adoption of the LuMiR system, in which key activities and their interdependencies were pointed out, and to organise a task force, in charge to support and monitor the adoption process. Actually, at the beginning the LuMiR project was mostly driven by the goal to develop and deploy a software platform implementation, nevertheless the additional efforts spent in disseminating and fertilizing the ICT-enhanced patient-centric idea, in supporting the redesign of more patient-centred primary care business processes, and in assisting and coordinating the software vendors for integrating their legacy application during the field study revealed even more important.

The design of LuMiR2 system, which will integrate data from the clinical documents into a VHR for each citizen, is in progress.

Experience Implementing OpenMRS to Support Maternal and Reproductive Health in Northern Nigeria

Adam Thompson[a], Evelyn Castle[a], Paul Lubeck[b], Provost Shehu Makarfi[c]

[a] *Global Information Internship Program sponsored by the Center for Global, International and Regional Studies at the University of California Santa Cruz*

[c] *Shehu Idris College for Health Sciences and Technology, Makarfi, Kaduna State, Nigeria*

Abstract

In Northern Nigeria a deteriorating health system has resulted in one of the World's highest rates of maternal and infant deaths. The dire situation in Northern Nigeria is only amplified by the lack of an effective health information system, leaving hospitals and clinics to make decisions about patient care with only uninformed guesses about medical history and access to unreliable and unintelligible patient registers and summary reports. In 2009 we implemented an electronic medical records system using OpenMRS for the Family Health Unit of the Shehu Idris College. The three-month process resulted in electronic forms for all clinical areas, greatly reduced data duplication and a monthly reporting process that takes minutes instead of days. This system provides not only access to the first patient-based health indicators in Nigeria (as opposed to previously error-prone aggregate data) but is also an example of the potential to overcome the harsh computing environment in Nigeria to implement eHealth systems that will improve the quality of patient care.

Computerized medical records systems, Nigeria, Reproductive medicine

Introduction

The Problem of Maternal/Child Health and Information Management in Northern Nigeria

The risk of a woman dying while giving birth in Nigeria is 1 in 18. In the poorer Northern parts of the country it can be as high as 1 in 13. For every woman that dies giving birth there are another 30 who suffer long-term and chronic ill health [1]. The story of child survival in Nigeria parallels that of motherhood with as many as 71 neonatal deaths in 1000 live births. A complete collapse of this system is only hindered by numerous NGOs and private foundations that in 2000 accounted for almost 90% of all health care spending [2]. While there now exist free or low-cost maternal and child health clinics, supported by several local and international agencies, these clinics are burdened by various paper-based "health information management systems". A typical data point is recorded 3-4 times and manually summarized monthly and quarterly. It can take weeks just to find the number of patients that attended a particular clinic. If it is not a research hospital or clinic (or specifically required to keep track by external funders) this information might not exist at all [3].

Towards a Viable Health Information Management System for Reproductive and Maternal Health with OpenMRS

To address the problem of maternal and child health and this crisis of information in Northern Nigeria, a team from the University of California Santa Cruz and the Shehu Idris College for Health Sciences and Technology (SICHST) put together an electronic medical records pilot at the Demonstration Clinic for the Family Health Unit (Asibitin Yara) in the Tudun Wada area of Kaduna. This pilot system, based on OpenMRS, is a complete clinical data system collecting information on antenatal visits, labor, child health, immunization and family planning. Between 60-100 clients and patients visit the clinic each week day and have their patient records created and updated without hindering or slowing patient care.

Methods

We describe the process to initiate a electronic medical records pilot and briefly explain how we identified the information "flows", technical literacy of clinical staff and the clinical use of computers and other technology. We then describe the process of converting the forms from each clinical area into OpenMRS, how the training was carried out, the design of the data entry procedures and how various technical and infrastructure issues were addressed.

Lastly, as of the writing of this paper, the pilot process is ongoing and in the process of expanding. We will describe the future expansion plans as well as plans to enhance the system to support clinicians at "point-of-care".

Results

A Clinical Information Needs Assessment

Beginning in June 2009, Evelyn Castle carried out an information needs assessment for staff of the SICHST Demonstration Clinic. The process began with a self-reporting survey to identify the use of information technology as well as skill and comfort level in both personal and clinical settings. The surveys were accompanied by in-context interviews and participant observation with ethnographic fields notes. Other clinical information needs studies have found the desire for "just-in-time" information at point-of-care and generally a need for ready access to patient-centric data [4, 5]. However in the Nigerian context there were significant barriers to information access including illegible handwriting, frequently missing patient cards, missing or broken equipment (ie for weight, blood pressure, etc) and social stigma especially around reporting HIV status, alcohol use and sexual history. These barriers resulted in a clinical culture where most types of data were rarely sought after, regularly seen as unavailable, and often not collected in the first place. The ONLY motivation for data collection, storage and reporting was because of mandate by the state government which sponsored this free clinic for women and children.

The SICHST Demonstration Clinic

The SICHST demonstration clinic is a government funded clinic in Tudan Wada, Kaduna. It provides free antenatal care, labor services, immunizations, child health care, family planning services, and reduced prices on pharmaceutical drugs.

Table 1 – SICHST staffing and workflow

Staff		Patients/Clients	
Doctors	0	Antenatal	60/day
Nurses	9	Child	40/day
Consultants	3	Immunizations	100/wk
Records Clerks	3	Family Planning	10/wk
Pharmacists	4	Labor	3/wk
Midwives	2		
Nannies/Guards	6		
Other Staff	3		

The staff at the clinic is made up of mainly women. Their age range is from straight out of school (22) to near retirement (65). The clinic is also frequented by young students doing practicals for their degree from SICHST. The technical experience of the staff is very limited. All of the staff owns a cell phone which they use frequently. The matron has a computer in her office, however she is unable to use it. Two of the Records Keepers have used computers in the past. Two of the consultants have used computers in the past and one is currently attending a computer programming class. Also, one of the pharmacists uses a computer for recreational purposes. Of the five staff members who are familiar with computers, 4 of them are male. No staff member had any knowledge of electronic medical record systems.

The use of technology in the clinic is non-existent. It contains one computer, which is not used. The only other technological devices it has is a television, a broken autoclave, a generator, and lights. The clinic receives light from PHCN infrequently and irregularly. When PHCN did supply power the voltage is too low to run many devices. The only reliable source of electricity came from the generator, which is often being refueled and repaired.

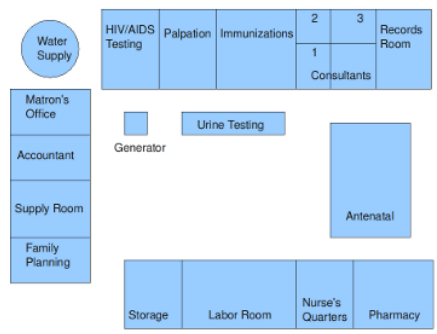

Figure 1-Layout of SICHST Demonstration Clinic

Clinical Records

Record Keeping at the clinic is all recorded on government forms or in hand-made log books.

Table 2 – Record keeping

Forms	Log Books
Antenatal, Immunizations, Family Planning, Child Health Care	Antenatal Check-in, Immunization, Out-patient register, labor and delivery

At the end of each month, the staff in charge of Record Keeping goes to each department and collects the information required by the Kaduna State Government. The information is gathered by going through the log books and counting each entry, one-by-one. The Kaduna State Government Monthly Summary consists of 7 pages with 76 questions, and 8 pages of tables. Each month the clinic is only able to supply answers to about one-third (1/3) of the questions.

Implementing OpenMRS

OpenMRS was quickly chosen as the platform from which to develop an electronic health information system to support maternal and child health because of it's existing deployments in similar low resource environments (ie Rwanda, South Africa and Kenya) [6, 7]. OpenMRS also existed in a range of deployment sizes from small clinics and large hospitals to networks of care centers. In addition OpenMRS was quickly able to be customized to support not only patient-based data

management but also aggregate data at the clinic, district and state level [8].

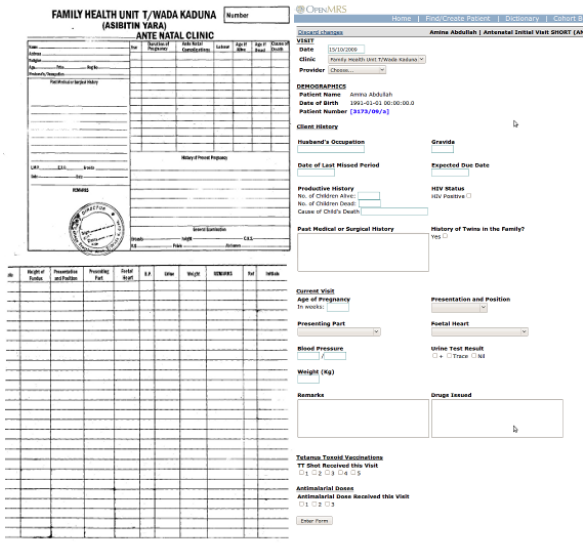

Figure 2- Antenatal Paper Card vs eForm

At the SICHST Clinic, the focus was to record Antenatal, Immunizations, Family Planning and Labor forms using OpenMRS. Two other departments, Child Health Care and Pharmacy would not be converted at this time since (1) there were no permanent paper forms and (2) in order to record these areas without extra burden, other equipment would be needed that there was not yet sufficient budget and training time.

The form conversion process did not result in an exact electronic copy of the paper form as is common for other OpenMRS implementations [7]. Instead since the patient cards were rarely completed in a correct or systematic way the electronic forms were made to match data that was ACTUALLY collected by the clinician. These electronic forms were revised over several iterations that involved simplifying data entry, adding drop down lists and check boxes whenever possible to speed up data entry. As well as creating alternative "short forms" to remove the clutter of other data fields that simply were not collected on the patient cards or registers.

To manage the data entry process a schedule was planned out after observing how the clinic runs and which services are offered each day. The volume of each service on particular days was such that the two data entry clerks could not keep up with the volume of data entry. Thus data entry was spread through the week and other staff that had computer skills would assist with back-log when time permitted.

	MONDAY	TUESDAY	WEDNESDAY
IMMUNIZATIONS	Enter all given today Enter all given Friday	Enter all given today	Enter all given today
ANTENATAL	Finish Thursday	Enter all from Monday	Enter all from Tuesday
LABOR	Enter all from Friday and over weekend	Enter all from Monday	Enter all from Tuesday
FAMILY PLANNING			

Figure 3- SICHST Demonstration Clinic Data Input Schedule

Reaction to OpenMRS and the Trainings

The initial reaction by the staff to OpenMRS was very positive. Most people at the clinic had never used a computer before but all claimed to be willing to learn. The people with past computer experience were more interested in learning OpenMRS.

Initially, training began with the two men in the Records Department, both who had previous experience with computers. They were able to understand OpenMRS and navigate the patient creation, patient look up and encounter form entry after only hours of introduction. The problems encountered while teaching were: language barrier, spelling errors, typing speed, and overall speed on computer. The clinic handles a large volume of clients each day and the overall speed of the two Records Keepers was not fast enough to record all the patients every day.

One of the causes of the overload of input data was because patients were coming for return visits. The Records Keepers not only had to input the information from the current visit, they were also required to enter the information from all the prior visits. We tried to combat this problem by focusing on entering in immunizations first (only the shots that children received during their current visit), then first time Antenatal clients, then second time Antenatal clients, and so on. Normally, we were able to finish all immunizations, and all first and second time Antenatal clients. However, in order for the Monthly Reports to give an accurate number of Antenatal clients and services, they will need to enter in the visits for all patients. This is projected to ease slightly with time as more and more of the clients/patients will have existing records in OpenMRS.

The other staff that received training were two women from Family Planning and two women from the Labor Department. After experimenting with teaching methods, it was concluded that it was most effective to have one of the men from Records do the teaching. The language barrier was too difficult to overcome and the staff seemed more at ease learning from one of their own colleagues.

OpenMRS Technical Setup

The computing environment even within the State's capital (Kaduna) proved to be very challenging. Another review of health informatics systems in Nigeria found the technical barriers to be the primary reasons for little to no adoption of these systems [3]. To combat the inevitable power and

maintenance issues, a simple setup was designed that used an OpenMRS server running on a single low-power Inveneo computer with a 500mhz processor, 1Gb RAM and a 40G hard drive. This server was connected to a network with another identical Inveneo machine. Another low-power ASUS Eee Laptop was connected via wireless when another data entry clerk was available. Both desktops were connected to battery backups that provide for two or more hours of work time when electricity from the "grid" or the generator were unavailable. Besides being simple to maintain, the equipment cost was under $1500 (USD). Other technical barriers revolved mostly around the clinic facility itself where several rooms did not have doors, locks, or correctly wired electrical outlets.

Discussion

Feedback from Clinical Staff

The implementation of OpenMRS proved to be very beneficial overall. Not only was the staff excited to learn OpenMRS, but they were also determined to keep the system running and up-to-date.

The clinic staff identified the following benefits of OpenMRS on their work in the clinic:

1. Saves time each month over gathering information manually
2. Gives an accurate report without human mistakes
3. Allows for more detailed analysis of data
4. Encourages staff to collect completed forms
5. Increase in clients because computers are associated with an advanced clinic

The feedback and buy-in from clinical staff was important early on. Having feedback rapidly implemented in the system created a high-level of personal and organizational investment into the system even after the main project implementors were no longer in-country.

Expansion Beyond the Demonstration Clinic: eHealth and Information Systems Nigeria

Nigeria is currently undergoing a public health crisis with regards to maternal and child health [9, 10]. In order to address this crisis, Nigerian clinics, hospitals and policy makers will need access to timely and accurate health information that can both influence policy as well as support patient care. To this effect it will be necessary to address the lack of an eHealth "ecosystem" in Nigeria. To support a robust health care information system, equipment vendors will need to exist that can provide low-cost, low-power equipment. Software and support service professionals will need to have the skills and expertise in implementing, customizing and extending platforms like OpenMRS. The authors of this paper are working towards these ends by (1) working with the SICHST to update a national diploma curriculum on Health Information Management Systems to include much more in-depth knowledge and hands-on experience with OpenMRS and other eHealth systems, (2) working with local vendors and software developers to understand the eHealth environment and provide equipment and services at reasonable costs and (3) creating effective partnerships with academic institutions, local and international NGOs as well as government institutions, to ensure a viable and sustainable health information system (see [11] for more discussion on creating effective eHealth partnerships).

Future Plans

Currently the Pathfinder International staff in Nigeria are evaluating our OpenMRS implementation and working with us to plan an expanded pilot in several clinics and hospitals that they manage and support financially. The goal is to have an "OpenMRS Nigeria Express" setup that will have ready to deploy hardware, software and power sources to extend the reach of important health informatics work into even rural parts of Northern Nigeria.

Conclusion

This project is a demonstration of the dramatic potential to revolutionize health information management in Northern Nigeria, possibly effecting millions of women and children over the next few years, with very little extra required in terms of resources, time and money. In many cases an effective and expanded use of OpenMRS will save time and money while opening up completely new possibilities for improved quality of care. The data collection alone will provide a never before seen view into the maternal and child survival crisis allowing the local and international community to come together and stay motivated and updated with important near real time information.

Acknowledgments

We thank the SICHST for all of their support and guidance as well as the entire team of the Demonstration Clinic that quickly took ownership and are committed to improving maternal and child health. We also thank Dr. Mairo Mandara for providing so much support and guidance. We thank the staff at Pathfinder International in Kaduna for showing interest early and providing helpful guidance and critique.

Abstract

Partners In Health (PIH) implemented an electronic medical record (EMR) system in Rwanda in 2005 to support and improve HIV and TB patient care. The system holds detailed patient records, accessible to clinicians through printed reports or directly via a computer in the consultation rooms. Ongoing assessment of data quality and clinical data use has led multiple interventions to be put in place. One such evaluation cycle led to the implementation of a system which identified 15 previously undiagnosed pediatric patients with HIV. Another cycle led to an EMR intervention which helped to decrease the proportion of completed critical CD4 lab results that did not reach clinicians by 34.2% (p=.002). Additionally an automated data quality improvement system reduced known errors by 92% by providing local data officers a tool and training to allow them to easily access and correct data errors. Electronic systems can be used to support care in rural resource-poor settings, and frequent assessment of data quality and clinical use of data can be used to support that goal.

Computerized medical records system, Developing countries, Information systems, HIV

Introduction

EMR in Rwanda

PIH has eight years of experience implementing EMR systems in resource-poor rural settings where meeting infrastructure, logistics and human resources needs is challenging [1,2]. The deployment of an EMR in Rwanda is a single intervention designed to meet multiple needs including improving direct patient care and decision making through access to summary chart data, printed summaries, using automated alerts and reports to ensure consistency of care and to aid follow-up. The system also allows the efficient production of aggregate data for administrative, monitoring and evaluation purposes, and to enable both research and reporting as required. Since the original implementation of PIH's EMR in Rwanda, the system has undergone numerous improvements and expansions. The current system is based on OpenMRS, an open source web-based EMR system that was co-developed by PIH and the Regenstrief Institute [3,4]. It is currently used in 16 PIH-supported health centers in Rwanda, as well as the government's HIV clinic in the capital city. By early 2010 the PIH Rwanda EMR held over 10,000 HIV, TB and heart failure patient records. This system is currently being expanded for general primary care use to support the Rwandan Ministry of Health's planned national implementation of OpenMRS across health centers.

Database setup

The EMR system is used in two provinces in Rwanda, and a separate database is maintained for each of these regions. In the Eastern Province, where solar power systems and internet access exist in the remote health centers, each health center runs a local server which is synchronized over the internet to the district hospital-based 'parent' EMR server. In the Northern Province, where electricity is not yet at all health centers, and only the district hospital has internet, data officers travel to the district hospital to enter the health center data into the shared database, and then return to the health centers with printouts of the upcoming week's consultation summaries.

Software Development

The PIH Rwanda EMR program currently employs two programmers who are based on site at one of the rural district hospitals, and develop modules and system improvements while immersed in the context in which the technology will be used. A key feature of OpenMRS is the modular nature of its architecture which allows programmers to develop and add additional functionality to the EMR without impacting on the code base of the system. This arrangement has allowed the software development to be adaptive, which is particularly beneficial in a complex low-resource environment.

Staffing

The organizational structure of the program is designed to maximize collaboration between PIH and the Ministry of Health (MOH) and build capacity within the MOH structures. All data officers who are based at the health centers, while currently funded by PIH because there is not yet a national EMR program, have employment contracts with the MOH. This allows the program to be part of the normal health center activities, which will increase the sustainability of the program. Employed by PIH centrally and providing support across all sites are a Data Quality Coordinator, Reporting Coordinator, Team Coordinator, Program Manager, Program Director, IT Officer and Software Programmers.

Data Collection

Almost all data collected by the EMR system is unambiguous, coded data. Collecting high quality data in the field is of critical importance to ensuring patient safety and quality of aggregate data. Input from clinicians, data managers, and researchers was incorporated into the design of the encounter forms that are currently in use in the field and are able to be updated to accommodate changing circumstances.

Clinical Use of Data

By prioritizing quality of care and placing an emphasis on clinician-oriented data tools, PIH's EMR program is currently working to maximize the amount of benefit from the system that flows back to clinicians, and therefore patients. In doing so, the system provides incentive for clinical staff to feel invested in the system and to prioritize accurate data collection as well as detection and correction of existing errors. Currently HIV clinicians at all 16 sites that use the EMR receive a printed consultation summary report each morning for patients scheduled for a visit that day. The summary sheet contains the patients' name, age, gender, program, three most recent recorded weights and CD4 counts, as well as their treatment regimen, and community health worker. An alert column indicates if the patient has a declining weight or CD4 count, and if their CD4 count is overdue. In addition to regular EMR reports, other data is provided to clinicians on request, such as lists of underweight patients, those at high risk requiring cervical screening, patients with renal failure. Lists of patients who are lost to follow up are provided to allow community health workers to make contact with the patients and encourage them to return to care.

Aim

The aim of this paper is to document the process of identifying areas within the electronic medical record program requiring improvement and implementing interventions to improve the quality of the patient data and to increase the usage of the clinical data for directly improving care in sixteen rural health centers in Rwanda. Brief case studies of four identified areas of need and the implementations and outcomes are described. These areas include decreasing errors in electronic data used by clinicians, improving transmission of CD4 results to clinicians caring for HIV patients, increasing clinician direct access to electronic patient summary data and increasing detection and program enrollment of HIV positive children.

Materials and Methods

Program auditing and process analysis were used to determine areas of the EMR program which could be modified to improve clinical care. The process in each case was the identification of needs through discussion with clinicians and the data team and analysis of existing data and workflow. Following identification of need areas the technical aspect of the intervention was undertaken, which included drafting necessary software tool requirements, and designing, developing and implementing the software though an iterative process between program manager, data team, clinicians and software developers. Other aspects of the intervention were also undertaken including provision of equipment, data officer training, clinician training and workflow adjustment. Each area identified for intervention was then evaluated.

Data Quality

This assessment focused on data which was directly used by clinicians for decision-making. In response to the identified needs, an automated data quality tool with emailed data quality report was developed for and implemented in OpenMRS. The developed tool allowed for customized definitions of data errors, for example people currently registered in the TB program that do not also have a current anti-TB drug regimen prescribed in their record. Each health center had a separate link to a data error report, which provided a real time list that linked to all patient files with a known data error. Additionally a weekly report was sent to the Data Quality Coordinator and data officers which listed the progress of data error correction in each site. Eight data errors types were defined and programmed in July 2009, and data officers and managers were trained to utilize these software tools to efficiently identify errors and initiate processes to correct them in collaboration with clinical staff when necessary. Incorporating input from data officers, a second round of error types were identified and automated lists were created.

To evaluate the impact of this intervention, the total number of errors detected was tracked on a monthly basis beginning with the implementation of the first automated lists. The total number of errors corrected was also tracked.

Access of laboratory results

The current process in place to support clinical decision making is based on patient summary data being available to clinicians along with alerts and reminders. Among the key variables for decision making for the clinicians that we support for HIV are patient drug regimen, weight, height, and CD4 count. CD4 count testing is a critical measurement to gauge the state of the patient's immune system and for clinicians to initiate antiretroviral HIV therapy (ART) or to identify treatment failure. Measurement of CD4 levels indicates how far the disease has advanced and the risk to the patient of complications or opportunistic infections. This test is usually performed every six months and is critical that clinicians be able to access the results of this test during a patient's consultation.

The existing method of communicating CD4 laboratory results to clinicians was identified as requiring improvement. The Rwinkwavu District Hospital laboratory processes CD4 count tests for two district hospitals and all health centers in the Kayonza, Kirehe and Ngoma districts in eastern Rwanda. CD4 count test result follow-up visits are scheduled a minimum of seven days after the test sample is obtained to allow sufficient time for transport of the test sample from the health center to the laboratory site and for sample processing and result return.

Before the introduction of the OpenMRS laboratory system, these paper-based laboratory results were entered into a static database on the laboratory workstation, which was stored locally and not integrated with the EMR system. Test results were then printed and transported back to the health center by hand or emailed to those health centers with internet connectivity available. At worst, printed test results were delayed in transit, and at best, clinicians were required to cross-reference

an individual patient's record with multiple laboratory result reports during the clinical visit to be recorded on the encounter paper form. Patients with lost ID cards often had a new patient record created in the laboratory system due to an inability to easily cross patient data in the EMR, making their CD4 data difficult to access.

Problems identified from this nonintegrated system were that clinicians did not always receive the most recent CD4 result on patient summary sheet printed from the EMR. The solution devised was to develop and implement a laboratory order and entry system in OpenMRS tailored to the clinic workflow, and to conduct a quality improvement evaluation. Based on a detailed requirements document, a new module for OpenMRS was developed to allow laboratory orders and results to be entered directly into the EMR system by data officers based in the Rwinkwavu laboratory and these results are being recorded directly into the patient's electronic record.

The usefulness of migration to the OpenMRS-based laboratory information system in reducing use of outdated CD4 count test results in assessments for HIV patients was also evaluated. Laboratory CD4 count test result data was collected from laboratory paper register logs for a 30 day period in January 2008, prior to the implementation of the OpenMRS laboratory system, and for an additional 30 day period in June 2009 following the completion of the implementation period. A period of one month was chosen based on power calculations which indicated a sample size of 474 would be sufficient for 80% power based on a 2 sided test with alpha = .05.

Each HIV patient encounter at the clinic required the clinician to complete a paper initial or return visit encounter form for the patient's chart – which included a space for recording the patient's most recent CD4 count. A CD4 result from the January 2008 and June 2009 date range was included in the sample if the patient with the test result also had a return visit encounter in the EMR and did not have an initial visit (where finding the initial CD4 is crucial to conducting the encounter) within 60 days after the test result. The clinical data was collected from the paper return visit encounter forms in the patient chart. For the purpose of this exercise, successful receipt of an up-to-date CD4 count test result was confirmed by a matching CD4 count value in the laboratory paper register as entered by the lab technician and on the return visit encounter paper form as entered by the clinician. Assuming the laboratory result registers are correct, this frame of analysis allows for the capture of all possible errors occurring throughout the transmittal process that could prevent successful delivery of the result. All cases of non-matching CD4 count values were investigated to attempt to identify the source of the error.

Data for all sites and for both pre-ART as well as ART patients were included in the evaluation. Exclusion criteria for patients with a CD4 result during either examination period were if a follow-up visit did not occur between 7 and 60 days following the test sample date, if the laboratory register recorded "no result," and if the patient had multiple CD4 counts in the 30 day period. The data was collected by EMR data staff with existing full access to patient medical records as part of their employment, and names were removed for analysis. Data officers were unaware of the CD4 count result from the lab register when recording the CD4 count that the clinician had written on the form.

Clinical Decision Making

After the conclusion of the intervention to improve access to laboratory results, the assessment was made that while an integrated laboratory system can help to improve the transmission of the data, relying on paper copies to be produced from the EMR still allows room for lost results. Patient consultation summaries were already being produced from the EMR that included brief pertinent information that could fit across a page and accommodate data for all patients scheduled to attend the clinic that day. This however did not account for patients who arrived at the clinic for an unscheduled visit. It was also limited to only providing a minimal set of information due to the format and space available. To expand clinician access to data for decision making, including access to graphs of key care indicators like CD4 count and weight, direct access to the system was required.

Training for HIV clinicians was conducted in June 2009 on how to log in to the EMR, look up patients, and use the data in patient summary. The training was led by data officers from several of the sites in which the clinicians work, so that they could serve as the onsite trainers when needed. Another required step for implementing direct look up was the purchase of laptop computers specifically for this purpose and configured and supported by the EMR IT officer for low maintenance (i.e., running Ubuntu, unneeded audio/visual componentry removed, locked to the desk). Due to a delay in acquiring the equipment, laptops were unable to be placed in all consultation rooms until September 2009.

A need was identified within the EMR program to assess if clinicians and data team were using the system to access patients files, how the system was being used, and to examine periods of heaviest system use. A usage auditing module was developed for this purpose, and deployed on one EMR server.

Targeted High Risk HIV Testing

A key benefit of the EMR system is the ability to automate real-time reports that would take many hours of work to compile under a paper-only system. A need was identified in enabling the EMR to support earlier identification of pediatric HIV cases in children of known HIV infected adults. The impetus for this is that early initiation of HIV care and ART in pediatric patients is associated with decreased mortality [5].

In April of 2008, an automated report was created to track untested children of HIV positive parents who were newly enrolled in the HIV program at any of seven PIH-supported health centers in Rwanda. If a parent's test result was positive, they are enrolled in an HIV treatment program and their paper intake form is entered into the EMR system. On a weekly basis, an automated report is produced that lists all children of HIV positive parents enrolled in the program who have not been tested for HIV as reported by their parent. This report is automatically emailed to the pediatrics department where the Pediatric Coordinator manages the database and the then work with the social workers and village-based community health workers to contact the family and have the child attend the health center for HIV testing.

Children who test positive are immediately enrolled in the pediatric HIV program, through which they are provided with comprehensive HIV care. To evaluate the impact of this intervention, the total number of children identified has been tracked on a weekly basis beginning with the implementation of the first automated lists. Of these children, the number tested and the number that tested positive was also tracked.

This study was approved by the Brigham and Women's Hospital Investigational Review Board

Results

Data Quality

The development and implementation of the automated data quality improvement tools, along with the training of data officers, led to a 92% decrease in eight pre-defined data quality errors (1064 errors corrected) in the first four months of implementation (Figure 1). Limits and ranges applied to concepts within the EMR identified existing errors including over 9,000 observation dates in the future, and will prevent such errors in the future. Feedback regarding use of the data quality OpenMRS tools was positive, and the training was well received by data officers. A user-friendly interface and automated weekly reminders have helped keep these tools in use.

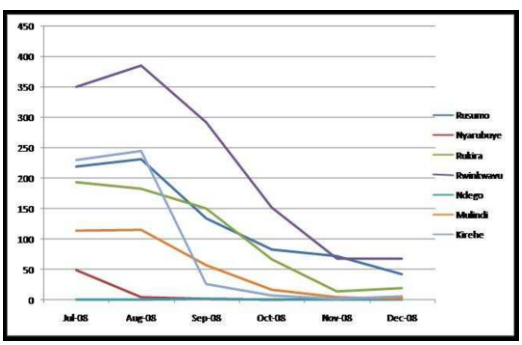

Figure 1 –Defined Data Quality Errors by Health Center Before and After August 2008 Data Quality Tool Implementation

Access to laboratory results

After patients who did not have a visit within 60 days of their CD4 test were excluded there were 457 patients in the January 2008 sample, pre-intervention and 545 in the June 2009 post-intervention sample. Exclusions due to incomplete charts and multiple CD4 counts in the same month decreased the sample size to 412 for and 493 respectively. The proportion of patients who completed CD4 counts within 60 days prior to their visit whose recent result was unknown to the clinician at the time of consultation was 24.7% pre-intervention and 16.7% post intervention, representing a 32.4% reduction in CD4 loss, a change which was found to be statistically significant ($p=.002$, $\chi^2=9.146$). There was no statistically significant difference for either sample period between lost CD4 counts and the age, gender or CD4 count range of the individual patients.

Clinical Decision Making

The response to clinician training on the EMR was positive, with over 30 HIV clinicians attending. In addition to this training, data officers at each health center were instructed to provide ongoing clinician support for computer and EMR use.

The equipment was successfully placed at each site and clinicians were able to access the EMR providing electricity and the local network were functioning. Prior to any additional formal training for clinicians, the usage audit tool was launched, showing that over a 21 week period between October 2009 and March 2010, 18 HIV and TB clinicians directly accessed the electronic records of 1752 patients. The number of patient records accessed ranged between two and 520 per clinician, with seven clinicians accessing over 100 records.

Targeted high risk HIV testing

In an assessment period covering six months the automated report of untested children with HIV positive parents resulted in 178 children being tested, with 41 currently awaiting results, 122 testing HIV negative and 15 who were found to be HIV positive. Due to their identification through the EMR, the HIV positive children are all now receiving comprehensive care, with seven of them receiving ART.

Table 1 – Summary of Audit Case Study Findings

Issue	Description	Intervention Method	Outcome
Data quality	Data errors existed in variables used for clinical care	Developed automated data quality tool and report and provided training	92% reduction in defined data errors
Access to laboratory results	Clinicians not having access to patients' most recent CD4 count during consultation.	Developed an integrated laboratory system in the EMR	32.4% decrease in CD4 counts that did not reach clinicians
Issue	**Description**	**Intervention Method**	**Outcome**
Clinical decision making	Clinicians not having direct access to comprehensive electronic patient summaries	Improvement of a patient summary module, development of an EMR-use audit tool, placement of laptops in consultation rooms	1752 patient records looked up by 18 HIV/TB clinicians in a 21 week period
High risk screening	Missing opportunity to used medical record data from HIV+ adults to ensure screening at their at-risk untested children	Developed an automated email report alerting weekly of any new untested at-risk	15 patients found to be HIV positive and enrolled in pediatric HIV program

Discussion

Each of the four areas of intervention led to a change in behavior and practice in the health centers. Efforts in training and changing workflows were very important in accomplishing this. In particular in each of these cases it was key to understand the user's needs, and ensure that a technological solution alone was not implemented. Data problems decreased sharply once data officers were aware of the existing problems. From this experience we learned that what is needed to continue to improve quality is to add additional pre-defined data errors to the data quality tools, and to increase automation of error reporting as well as primary prevention of data errors. Similarly with increasing detection of the pediatric HIV patients we saw that this type of report being automated from the EMR, with a documented process of what actions are taken when the report is received, can lead to improved program quality and have real clinical impact. Automated high risk patient screening reports are likely to have a clinical impact, provided that the processes and workflows surrounding them are sustainable.

Clinician access to information was addressed in both increasing access to laboratory results and allowing direct lookup of patient data. In this regard many of the hardware and software challenges have been overcome, but training clinicians on using the system and ensuring it is designed to respond to the clinician's needs remain the challenges. In particular there was a long unintended gap between training clinicians on looking up patients in the EMR and in providing the equipment for them to be able to do so. Some clinicians used the system only infrequently, and discussion with them will be required to better understand if there are hardware, software, training or workflow changes that could increase the usefulness or ease of use of the system. Due to the development of the audit module as part of this process, it is now possible to observe if there are changes following trainings or after the addition of clinician-requested features to the EMR. An additional need for a re-evaluation of clinician access to CD4 counts will take place after the clinicians have had further training on direct access to the system. Establishing a cycle of audit and quality improvement in the EMR program will allow for faster progress towards having the most effective and useful system possible.

Conclusion

Multiple strategies have been employed to improve EMR data quality and use of the data to improve patient care. Experience from the capture of HIV, TB and chronic care patient data has shown that as the PIH OpenMRS program in Rwanda continues to expand, in particular to include capture of all primary care data, the need for automated and user friendly tools to assist in data quality and clinical care will increase.

Acknowledgments

The authors would like to acknowledge the CDC for the provision of funding to assist PIH in the development of some of the described software modules, hardware purchases, and support for quality improvement activities. We would also like to thank Marc Harrison, Michael Seaton, Rowan Seymour and Chase Yarbrough for the development of the OpenMRS intervention tools, Lisa Hirschhorn and Ann Miller for support with study design, and the clinicians and EMR data officers who participated in these quality improvement activities.

Key Common Determinants for Adoption of Wireless Technology in Healthcare for India and Pakistan: Development of a conceptual model

Abdul Hafeez-Baig and Raj Gururajan

School of Information Systems, University of Southern Queensland, Toowoomba, Australia 4350

Abstract

This study explores the perception and views of healthcare professionals in the subcontinent (India and Pakistan) towards the wireless handheld technology in the healthcare setting. A mixed methodology was adopted to explore the determinants of the wireless handheld devices in the healthcare setting. Interviews were conducted with 30 healthcare professionals to explore the initial themes. This was followed up with a survey instrument, specifically developed for this study, and distributed to 300 healthcare professionals in Pakistan and India. 200 useable surveys from India and 97 from Pakistan were received. The results of the study indicate that healthcare professionals felt that to use the wireless technology, the integration of the clinical and operational process is essential. Factor analysis through SPSS showed that any development of technological solutions for handheld devices would benefit, by considering the clinical, technological, and operational influences of the wireless technology in addition to clinical influences, clinical preference, training, and technical support. The study culminated in the development of an initial conceptual framework. The scope of this study is restricted to wireless handheld devices such as the smart phones, handheld PCs and PDAs.

Keywords:

Wireless technology, Healthcare, PDA's, Handheld

Introduction

Technology Acceptance Model (TAM) asserted 'perceived ease of use' and 'perceived usefulness' as the determinants in predicting the acceptance of technology in a given setting. These constructs were found reliable in many Information Systems studies. However, when these models were tested in a healthcare environment, the perceived ease of use was not found to be significant [1, 2]. Furthermore, other studies also established that the perceived ease of use was not a significant predictor of technology acceptance in specific clinical domains [3, 4]; Hu et al., [5]. While studying the dynamics of IT adoption in a major change process in health delivery, TAM was found inadequate [6]. In introducing electronic patient records into hospitals, it was found that relative advantages, available strong network externalities, and the rich availability of information through different communication channels influenced technology adoption [7]. While measuring the physician's understanding of online systems use, the physicians' behaviour, their workflow practices and their perceptions regarding the value of specific information systems were found to be more significant than the perceived ease of use and perceived usefulness [8]. Therefore, there is a need to revisit the factors that determine the adoption of wireless technology in healthcare.

Research Problem/Design

Literature identified various factors that can influence the acceptance/usage of wireless handheld devices in the healthcare environment. For example, mobility, real time access, reduction in cost, improved patient care, and reduction in error [9-14] are factors identified using wireless technology in terms of improving healthcare. There are limited studies that have investigated the views and opinions of healthcare professionals in terms of wireless handheld devices in the Indian and Pakistani healthcare environment. In order to identify themes that may be applicable to the Indian and Pakistani environment, we conducted a set of 30 interviews in the Indian healthcare environment. We omitted Pakistan from the interviews as the two countries come with similar healthcare settings and it was convenient for the interviews to be conducted in India. Participants for the interviews were selected from private and public hospitals that were involved with patient care and had some exposure to wireless technology. In order to ensure the interviews were conducted on time, the local health district was approached by an author of this paper and suitable candidate groups were identified. The interviews were conducted in such a fashion as to minimize any disruption to the participants' work schedule, to ensure comfort in answering questions, to minimize any travel time by interviewees, to synchronize the 'interview' language with participants and to prompt participants when unknown aspects were encountered by participants. Prior to the interviews, the line managers were approached for permission to release staff for the interviews. Initially a consent letter was distributed to obtain consent for interviews and the list of people to be interviewed was provided to the Health District. The interviews were recorded using a digital recorder and

catalogued as per the ethical requirements. These interviews were then transcribed for data analysis. Participants for the interview were selected from the healthcare professionals in the Southern Region of India. The participants were initially screened for suitability, and previous workings with technology were considered for this purpose. Any staff involved with 'administration only' was eliminated from the interviews to avoid any unforeseen bias. As the healthcare professionals belonged to the Health Department, no further screening was employed for the sampling.

The instruments of this research consisted of two broad categories of questions. The first category of questions was related to the adoption and usage of wireless devices in hospitals for data collection purposes. In this category, questions were asked in terms of usage, perceived benefits, perceived problems, management issues, performance issues and operational aspects. The second category consisted of demographic variables. Open-ended questions were included in the instrument to obtain unbiased and non-leading information. Prior to administering the questions, a complete peer review and a pilot study were conducted in order to ascertain the validity of the instruments. The specific research problem investigated during this stage of the study is as follows

- What are the factors of acceptance of wireless technology in a healthcare environment for India and Pakistan?
- What are the emerging challenges in adopting wireless handheld devices for the Indian and Pakistani healthcare environments?

Survey Data Collection

In order to extract opinions about technology in a specific domain such as healthcare, the choice of sample is crucial. This is because the opinions expressed by healthcare professionals should be unbiased and should pertain only to the technology and not the effects of the technology on their current workflow. The samples for this project were drawn from the health department of both Pakistan and India, where each participant is currently holding a practicing license. Furthermore, the participants chosen were working in clinical wards. People in administrative roles were eliminated from this stage to avoid any unforeseen bias. While Information Systems research identifies a range of sampling techniques such as random and clustering, the sampling technique used for this study was 'purposive' sampling. As healthcare staff with special knowledge of technology were needed, this sampling technique was employed in this study. The samples were chosen through the local medical district on their advice as their opinions on wireless technology were extracted based on their knowledge. Therefore, the samples needed to exhibit certain attributes that are related to technology adoption.

This study developed a specific survey instrument from the interview data. The main reason for this approach was that previously tested instruments were found to be inadequate in the healthcare settings of Pakistan and India. The data from the interviews was used to develop a specific range of questions to gather a more detailed view from the wider population, such as the usefulness of wireless handheld devices in healthcare, participants' knowledge of wireless handheld technology, their views about error reduction and cost reduction, and the clinical efficiency as well as performance factors. This survey instrument (contains 5 point likert scale) was pilot tested to capture the information reflecting the perceptions and practice of those adopting the wireless technology in the Pakistani and Indian healthcare system, particularly focused on what internal and external environmental factors shape the adoption of wireless and the extent of influence.

This survey was then randomly distributed to over 300 healthcare professionals from the Southern Region of India, and in the Punjab province of Pakistan. A cover letter explained the objectives and goals of the research. In order to improve the response rate a telephone reminder was sent two weeks after the initial date of survey distribution. A total of 200 surveys were received from India and 97 were received from Pakistan. When the instrument was tested for reliability, the Cronbach Alpha was over 0.89, confirming reliability. Table 1 provides a summary of the demographics. It can be inferred from the table below that for the Pakistan sample, there was an equal number of males and females, and the median experience was less than 10 years, as most of them had a bachelor's qualification, and many of them were under 25 years of age. The demographics for the Indian sample were inconclusive as many participants did not fill in this information.

Table 1- Summary of demographic data

Category	Descriptions	Pakistani	India
Gender	Male	50.5%	70%
	Female	49.5%	30%
Education	Bachelor degree	73.2%	50%
	Diploma/Certificate	4.1%	16%
	Other	10%	15.5%
Experience	Less than 2 years	17%	27.5%
	Less than 10 years	69%	51.0%
	More than 10 years	11%	20.5%
Age	Less than 23	52.6%	40.9%
	Between 23 and 29	26.8%	17.0%
	Between 30 and 36	10.3%	5.5%

Once the instrument was found to be suitable, a factor analysis as "Principal Component Analysis" with "Varimax Rotation" was run on the data. Results of the factor analysis for the Indian sector are shown in Table 2, below.

CP = Clinical Performances, CM = clinical management, and TB = Technology Barrier

The Indian data returned three factor groupings. These factors were titled clinical performance, clinical management, and technology barrier. Similarly, the factor analysis as "Principal Component Analysis" with "Varimax Rotation" was run for the Pakistan data and resulted in three specific factors, namely data management, clinical performance and usage barrier as is shown in Table 3. As a result of factor analysis, the initial framework did not distinguish among positive and negative factors and did not incorporate the mediating factors either, as this was not the scope of this paper.

Combined Pakistan and India Data Analysis

We also conducted an exploratory factor analysis to investigate the combined data. The combined data resulted in four distinct factors, namely clinical performance, clinical data management, technology barriers, and clinical communication. When a correlation analysis was conducted, most of the factors correlated with their group items positively and significantly, indicating the cohesive nature of these groupings. As the nature of the study is exploratory, once the data reduction technique was adopted, the factor analysis was saved as component factors with the following labels: Clinical Performance (CP), Clinical Data Management (CDM), Technology Management (TM), Clinical Communications (CC) and the predictor variable Intention to use (ITU). The strategy was to combine related items of the factor analysis into a single item. Further before conducting the regression analysis, a correlation analysis was conducted among the independent variables CP, CDM, TM, CC, and the predictor variable ITU.

As can been seen from Table 4, the correlation analysis shows a low correlation among the independent variables. The correlation between the composite variable is positive and is not significant ($r < .5$ and $p < .05$), where as the correlation for the composite variable technology management and the predictor ITU is low with a negative direction ($r < .5$ and $p < .05$). Therefore, multicollinearity does not exist for the composite variables, and according to [15] multicollinearity exists only if there is a strong correlation between the independent variables (as $r < .5$).

Table 4- Summary of correlation (2-tailed) analysis

	ITU	CP	CDM	TM	CC
Intention to Use	1.000	.791**	-.030	-.285**	.087
Clinical Performance	.791**	1.000	.000	.000	.000
Clinical Data	-.030	.000	1.000	.000	.000
Technology	-.285**	.000	.000	1.000	.000
Clinical	.087	.000	.000	.000	1.000

To understand the role of each composite variable and to explain the variation in the predictor a regression analysis was conducted. The linear regression analysis was conducted as the "Enter" method with ITU as the dependent variable and CP, CDM, TM, and CC as dependent variables to understand the variation in the ITU. The 61.2 % variation in the ITU is explained by the predictors CP, CDM, TM, and CC ($R = .786$ and Adjusted R-Square is .612). From the regression analysis, independent variables "Clinical performance", "Technology management", and "Clinical Communications" for the subcontinent healthcare professionals are quite significant and uniquely contribute to their views about uses of wireless handheld devices in a healthcare setting ($\beta = .74$, $t = 20.3$, $p < .05$, and $\beta = .08$, $t = 2.2$, $p < .05$). Whereas the independent variable "Clinical data management" seems to not be providing any unique contribution in explaining the healthcare professional intention to use wireless handheld devices in the sub-continental healthcare environment ($\beta = -.03$, $t = -.8$, $p > .05$). Once it was clear that the independent variable CDM was not contributing to explaining the variation in ITU wireless handheld devices, another linear regression without the CDM variable was conducted and the regression results were not much different from the previous analysis ($R = .79$, Adjusted R-Square = .613, df (293,3) = 157, $p < .05$ and $\beta = .74$, $t = 20.3$, $p < .05$, and $\beta = .08$, $t = 2.2$, $p < .05$). The standardized coefficient of multiple regression analysis provided the relationship of the independent variables (CP, CDM, TM, and TM) for the dependent variable of intention to use wireless handheld devices for the subcontinent's healthcare environment.

The above framework shows the relationship between the dependent and independent variables, the analysis shows that healthcare professionals in the subcontinent see variables such as "clinical performance" and "clinical communications" as having a positive effect on the intention to use the wireless handheld devices in the healthcare setting.

Discussion

The data analyses indicated that clinical performance and clinical data management are common to both countries. However, as can been seen, both countries have concerns about the barriers. Indian healthcare professional perceived the existing status of the wireless handheld technology itself posing some barriers, whereas, Pakistani healthcare professionals perceived the barriers in terms of usage context. In the combined context, communication is an additional factor contributing to the usefulness of wireless technology in healthcare. The combined data clearly indicates the clinical performance, clinical data management and technology barriers to realize the usefulness of wireless technology in a healthcare domain as the three main contributors of acceptance of wireless technology. This indicates that in order to be accepted, technology should be useful in a given context. In terms of clinical performance, the factors such as reduced workload [8], the saving of time [16], the reduced overall cost [17], the reduced medical errors [18], the reduced inaccuracies [19] and the easy access to data [20] have already been identified in the literature. This study has confirmed these factors, perhaps for the first time, using empirical evidence. However, factors such as improved public image and improved clinical performance attract more practitioners, more contact time with patients, better quality of service and the delivery of high quality information are new factors. The set of these factors indicate that medical staffs perceive the wireless technology to provide direct benefits in these areas in order to realize better clinical performance. These respondents have also identified the positive-impact-on-patient-safety in addition to the above factors, subtly indicating their concern on patient safety due to the current inferior standards of data quality. These factors are new and have not yet been established in the literature.

In terms of technology barriers, this study established system migration, benefit evaluation, time for training, poor technology, incomplete health standards, legal, technical expertise, technical support, security, device usage, device comfort and device access as barriers to the clinical usefulness of wireless technology. While some of the factors such as the poor technology have been identified in the literature, the device access and device usage aspects are surprising. One would expect that due to the relative affordable cost of the devices, access and usage would be drivers rather than barriers. The views expressed by the respondents indicate this not to be the case. This may be due to the fact that the current health system budgets are predominantly allocated to salaries and clinical services rather than investment in technology. One would expect that by investing in technology and the prevalence of telemedicine concept, it would be possible to reduce the queues in hospitals. This does not appear to be the case. The third set of factors, clinical data management, is interesting because for the first time certain specific factors were identified to highlight the usefulness of wireless technology for healthcare. These factors include medical database referral, electronic prescribing, obtaining lab results, note taking, and drug administration. While previous studies have highlighted the usefulness of wireless technology, most of them have focused on the management aspects, clinical usefulness was very seldom covered in the literature. This study has identified specific factors that contribute to the usefulness of wireless technology in a clinical setting. In addition to identifying these factors, this study was able to identify the common factors between two radically different medical systems, namely India and Pakistan. Despite the relative differences between the countries, this study has been able to establish a set of common factors that bind the clinical usefulness factors of wireless technology for these two healthcare systems.

Conclusion

It can be concluded from this study that technical, clinical and management/operational factors are the driving force behind the intention of the healthcare professional to use the wireless handheld technology in the subcontinent.

It can be also be summarized that drivers are the factors with the potential of improving the clinical process and

management of the patient care, and the inhibitors are due to lack of wireless solution, infant stages of the technology, and management support. There is clear evidence that healthcare professionals in the subcontinent are motivated and keen to use the wireless handheld technology in the healthcare environment. This study has identified factors such as clinical performance, clinical management, clinical communication, and data management as major factors for the intention to use wireless handheld devices. The main challenge that has emerged from this study is that even though healthcare professionals are motivated, they would like to see the usefulness of the technology and availability of the appropriate healthcare applications for wireless handheld devices.

Future studies can use these factors in order to develop a regression model so that the factors identified can be regressed into a smaller set. The main purpose of the study was to identify initial factors and hence the data collected was not found to be suitable for a second order regression model. Therefore, this was not attempted in this study.

Factors associated with health information system success: Results of a survey of hospitals in South Africa

Lyn A Hanmer[a], Sedick Isaacs[b], J Dewald Roode[c]

[a] *eHealth Research and Innovation Platform, South African Medical Research Council, Cape Town, South Africa*
[b] *HealthTechSA, Cape Town, South Africa*
[c] *Department of Information Systems, University of Cape Town, Cape Town, South Africa*

Abstract

A survey of computerised hospital information system (CHIS) use was conducted in two South African provinces, in order to test a conceptual model of CHIS use developed in previous phases of this study. Relationships between factors of the conceptual model and user assessment of CHIS success; and between pairs of conceptual model factors, were derived from the survey data.

The results confirmed that factors of the conceptual model were associated with CHIS success. Analysis of the relationships between factors yielded results which supported some of the conceptual model relationships, and were inconclusive for others. None of the conceptual model relationships was contradicted by the survey results. Further investigation is required to demonstrate statistical relationships between factors of the conceptual model more conclusively.

The results to date support arguments for the applicability of the conceptual model of CHIS use beyond the study hospitals to other level 1 and level 2 hospitals in South Africa.

Keywords:

Hospital information system, South Africa, HIS evaluation, HIS success.

Introduction

Studies of factors associated with the success and/or failure of computerised health information systems have focussed on the factors themselves, and the relative weighting of the factors, rather than on the relationships between factors ([1] and [2] for example). In this study, factors associated with success; user assessment of success; and the relationships between factors associated with the success of computerised hospital information systems (CHISs) were examined.

In previous phases of this study, a conceptual model of CHIS use was developed based on case studies in four South African hospitals, as reported in [3] and [4]. A survey of CHIS use was conducted in level 1 and level 2 hospitals in two South African provinces, in order to test this conceptual model of CHIS use. The model is shown in Figure 1.

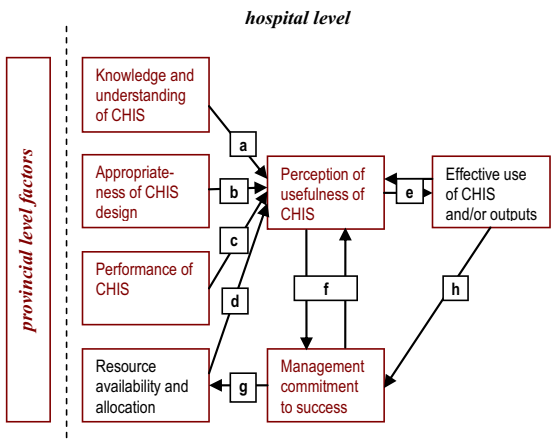

Figure 1- Conceptual model of CHIS use, identifying relationships between model factors for analysis

Methods

A survey of CHIS use was conducted in level 1 and level 2 hospitals in two provinces in South Africa. The objectives of the survey were

- To review the factors of the conceptual model of CHIS use;
- To further investigate relationships between factors of the conceptual model of CHIS use;
- To identify differences between groups of hospitals using the same CHIS in respect of factors associated with CHIS success or lack of success;

- To provide further data for identifying factors which could help to explain CHIS success or lack of success.

Two sets of questionnaires were used: hospital questionnaires were designed to obtain information about the CHIS implementation for the hospital as a whole, and user questionnaires were designed to obtain the opinions of individual users. Questions in the questionnaires were designed to reflect various aspects of the conceptual model. Extensive provision was made in the questionnaires for user comments. Quantitative data took the form of weighting on a 5-point scale (strongly disagree, disagree, neutral, agree, strongly agree) or presence or absence of a factor (yes, no, neutral). Provision was made for recording 'no response' to questions.

Data were collected from a wide range of CHIS users, including heads of hospitals, information officers, case managers, and supervisors of end users. Interviews were conducted in person or telephonically by arrangement, and the questionnaires completed by the interviewer; or questionnaires were self-completed by the respondents.

Results

Overview of the CHIS implementations

Data were obtained from 70 respondents at 30 hospitals in the two study provinces. The CHIS implementations in the study hospitals supported patient administration and billing, and included provision for recording limited clinical data. The study hospitals in Province 1 were using one of two CHISs (SystemA or SystemB) and all the study hospitals in Province 2 were using SystemC.

Data analysis approach

A major aim of the survey was to build on the results from the case studies, in order to further refine the conceptual model of CHIS use as a framework for analysing CHIS success. The analysis of the survey results was aimed at investigating the validity of the conceptual model in the survey hospitals (i.e. in additional level 2 hospitals in Province 1; in level 1 hospitals in Province 1; and in level 2 and level 1 hospitals in Province 2), and assessing whether changes in the model would be required (based on the survey results).

In general, data analysis was done by treating all respondents using the same CHIS as a single group, in order to work with a reasonable sample size (maximum 33 respondents for SystemA, 15 for SystemB and 24 for SystemC). Hospital data were combined in such a way as to reflect the overall view of the data from a hospital perspective.

Due to the limited sample size in relation to the number of variables being considered, it was not possible to use analytical statistical techniques for data analysis. Therefore, a descriptive statistical approach was followed to describe the results related to the factors in the extended conceptual model of CHIS use; and to compare and discuss the relationships between model factors as reflected in the survey results.

Conceptual model factors associated with CHIS success: User responses

Some of the survey questions were designed to obtain the respondents' opinions about the association between the **hospital-level** factors in the conceptual model and CHIS success; and between these conceptual model factors and lack of CHIS success. The factors associated with lack of CHIS success were conceptualised as being the opposite of those associated with success (i.e., lack of knowledge and understanding, inappropriate design, poor performance, etc.). A summary of user responses to questions related to the factors in the extended conceptual model of CHIS use, from users in Provinces 1 and 2, is given in Table 1.

Respondents appeared to find difficulty dealing with these questions relating to factors associated with success and lack of success, and particular difficulty with factors associated with lack of success. On average, there were 32% nil or neutral user responses to the questions related to CHIS success (see Table 1) and 42% nil or neutral response to questions related to **lack of** CHIS success. Possible explanations for the difficulties experienced with these questions include the phrasing of the questions, and a lack of general knowledge and experience of CHISs among some of the survey respondents, although conclusive evidence was not obtainable.

Table 1 - Rating values for factors associated with CHIS success – all users all hospitals

Conceptual Model Factor	Total users	Users no response/ neutral	-ve user response	+ve user response	% +ve user response
knowledge	72	23	1	48	98%
design	72	23	3	46	94%
performance	72	23		49	100%
resources	72	22	5	45	90%
usefulness	72	23		49	100%
commitment	72	24	3	45	94%
use effectively	72	23		49	100%
Average		**32%**		**68%**	**97%**

Taking into account the limitations in this data set, those respondents who did express opinions about the association between the (hospital-level) conceptual model factors and CHIS success in their environments agreed that there was an association between the conceptual model factors and CHIS success: Overall, approximately 97% of the respondents to these questions agreed that the factors in the extended conceptual model of CHIS use are associated with CHIS success. A few respondents indicated that these factors are not associated with CHIS success. These negative responses could be interpreted as meaning that, in the respondents' environments, these factors were not associated with CHIS success due to their absence or weakness (limited resources, or limited management commitment, for example). On average, 65% of the respondents strongly agreed or agreed that **lack of** each of the factors of the

conceptual model could be associated with lack of CHIS success in the hospitals in which they were working. Therefore, the available data do support the inclusion of the hospital-level factors in the conceptual model of CHIS use developed in this study as being factors associated with CHIS success. The converse, i.e. that lack of these factors is associated with lack of CHIS success, is less strongly supported by the data.

Although the number of respondents for which data are available is limited (average 47 respondents about factors associated with CHIS success and average 42 respondents about factors associated with lack of CHIS success), this is also true of other studies examining the factors associated with CHIS success or failure, such as those in [1], [2] and [5]. Future studies which include more respondents would enable stronger conclusions to be drawn.

Conceptual model factors and user perception of CHIS success

The variable 'successful?' reflects the responses of users to the statement 'Overall, in terms of my job, the CHIS is a success'. The rating values of this variable therefore provide the most direct reflection from the survey of the respondents' overall opinions of the CHIS which they were using.

One of the assumptions in this study (also supported by results from the literature) is that effective CHIS use is related to CHIS success. Therefore, if the conceptual model is valid, the rating values (and other measures) of the factors of the conceptual model of CHIS use, should be consistent with user perceptions of CHIS success in their working environments. The analysis of cross correlations between the variable reflecting CHIS success ('successful?'), and the variables reflecting factors of the extended conceptual model of CHIS use, was therefore aimed at exploring these relationships, based on the available numeric data from the study survey.

At hospital level, there were statistically significant correlations between 'successful?' and the variables linked to the conceptual model factors 'quality of data' (sub-factor of 'knowledge and understanding of CHIS'); 'performance of CHIS'; 'perception of usefulness of CHIS'; and 'effective use of CHIS and/or outputs'; respectively for some categories of users. At user level, there were statistically significant correlations between 'successful?' and the variables representing each of the model factors, for some categories of users.

Apart from counter-intuitive results for SystemB users, the results of the cross correlations at user level between 'successful?', and the variables representing the following model factors supported the corresponding relationships in the extended conceptual model of CHIS use: 'knowledge and understanding of CHIS'; 'appropriateness of CHIS design'; 'perception of usefulness of CHIS'; and 'management commitment to CHIS success'. The correlations between 'successful' and 'effective use of CHIS and/or outputs' were counter-intuitive or weak, in contrast to the strong correlations between these variables at hospital level. As for the hospital-level analyses, the results at user level did not support a relationship between 'successful?' and the variable representing the factor 'resource availability and allocation' in the conceptual model.

The hypotheses that the factors of the conceptual model are associated with CHIS success are thus largely supported by these cross correlations.

CHIS success: variables associated with factors of the extended conceptual model of CHIS use

Following the argument that the factors in the conceptual model are associated with CHIS success, the percentage of positive rating values for the variables representing these factors provides an indication of level of success. Therefore, the rating values were analysed, mainly at user level, for each of the variables used to reflect the hospital-level factors of the conceptual model. For the variable which reflects the resource allocation for ICD-10 coding from patient records, rating values were analysed at hospital level. A summary of the percentage positive rating values for the variables used to represent hospital-level factors in the extended conceptual model of CHIS use is presented in Table 2.

Table 2 - Summary of % positive responses for measures of conceptual model factors

Conceptual model factor	SystemA Prov 1	SystemB Prov 1	SystemC Prov 2
Knowledge and understanding of CHIS - training	92%	85%	65%
Knowledge and understanding of CHIS – quality of data	68%	46%	47%
Appropriateness of CHIS design	84%	69%	33%
Performance of CHIS	100%	68%	41%
Availability and allocation of resources (per hospital)	***38%***	***20%***	***71%***
Perception of usefulness of CHIS	89%	60%	64%
Management commitment to CHIS success	93%	80%	42%
Effective use of CHIS and/or outputs	75%	43%	33%
Respondents' perceptions of CHIS success	***95%***	***100%***	***37%***

For the purposes of comparison, the 'percentage of positive responses' was calculated for each variable, for each category of users. The 'positive responses' reflect all responses which reflect a positive response in terms of CHIS use. The percentage of positive responses was calculated using the total number of responses to the question as the denominator (i.e., excluding the number of 'no response's (rating value = 9)).

Apart from the data for 'availability and allocation of resources', these data for percentage positive rating values show that the survey respondents regarded SystemA as being more successful than either SystemB or SystemC, and that the two Province 1 implementations (SystemA and SystemB) were viewed as being more successful than the SystemC implementations in Province 2. This pattern is repeated in respondents'

perceptions of CHIS success, as reflected in the user responses to the question 'Overall, in terms of my job, the CHIS is a success', as shown in Table 2. All but one of the respondents among the SystemA users, and all the SystemB users, who responded to this question agreed or strongly agreed that the CHIS was a success in their jobs, while only 37% of SystemC user respondents shared this opinion.

Statistical analysis: relationships in the conceptual model

Eight relationships between factors in the extended conceptual model of CHIS use were analysed, reflecting the relationships between factors in the extended conceptual model of CHIS use, as shown in Figure 1.

The relationships between the characteristics of users and the CHIS and perception of usefulness of the CHIS (relationships (a) to (c)) were generally not strongly supported by the results of the cross correlations. However, the data from cross tabulations between the rating values of these variables did support these relationships.

Positive, but not statistically significant, cross correlations were shown between 'all patients' (reflecting resource availability for ICD-10 coding) and 'management commitment to CHIS success' (relationship (g)). A weak cross correlation was demonstrated between 'all patients' and 'perception of usefulness of CHIS' (relationship (d)).

Strong, but not necessarily statistically significant, relationships were demonstrated for most groups of respondents for the measures for the relationships involving 'management commitment to CHIS success', 'effective use of CHIS and/or outputs' and 'perception of usefulness of CHIS' (relationships (e), (f) and (h)). Where cross correlations were counterintuitive, cross tabulations did reflect positive relationships between these variables, as expected in terms of the conceptual model. The measures used for these conceptual model factors at hospital level all related to the respondents' perceptions of hospital management attitudes to and use of the CHIS at a hospital. The cross correlations between these variables were generally stronger than those for other conceptual model relationships, reflecting support for the relationships in the model. In a future study, more detailed comparisons between the answers to these questions by different groups of respondents could provide interesting insights into differences in perception of the CHIS between groups of hospital personnel.

Discussion

The aim of this survey was to test and refine the extended conceptual model of CHIS use developed following the case study phase of the study. The data from the survey were analysed from two perspectives: testing of hypotheses related to the relationships between the factors in the extended conceptual model of CHIS use, and CHIS success; and testing of hypotheses related to the relationships among factors in the conceptual model. The presentation and analysis of results in the previous Sections focussed largely on the results of analysis of the numeric data from the survey. In this Section, some of the available numeric and non-numeric data from the survey are discussed in combination.

Relationships among factors in the extended conceptual model of CHIS use

Results of analyses of data related to factors, and relationships between factors, in the extended conceptual model of CHIS use have been presented. Relationships between 'perception of usefulness of the CHIS' and other factors of the conceptual model; and data related to 'resource availability and allocation' are discussed further in this Section.

Perception of usefulness of CHIS

This factor of the extended conceptual model of CHIS use is linked to all other hospital-level factors in the model, reflecting the strong influence of perceptions on users' attitudes to CHISs. As discussed previously, there were few statistically significant cross correlations between the variable used to represent 'perception of usefulness of CHIS' and measures of other factors in the conceptual model.

Respondents were also asked a series of questions about the CHIS which they were using. The responses to these questions were coded in terms of factors of the conceptual model, yielding a set of approximately 300 coded comments from all the users who responded to these questions.

The coded comments linked to positive perceptions of usefulness of the CHIS related mainly to the model factors 'appropriateness of CHIS design' (approximately 50% of coded comments); 'knowledge and understanding of the CHIS'; 'CHIS performance'; and CHIS outputs (a sub-factor of 'effective use of CHIS and/or outputs'), and confirmed relationships between these factors and 'perception of usefulness'. For the coded comments linked to negative perceptions of usefulness of the CHIS (fewer than 100 coded comments), the majority of comments were related to 'CHIS performance' and 'appropriateness of CHIS design', thus supporting a relationship between poor CHIS performance and/or design, and a perception that the CHIS is not useful.

Combining all available data related to 'perception of usefulness of CHIS', it can be claimed that the relationships between this factor and factors related to the CHIS implementation ('knowledge and understanding of the CHIS' by users; 'CHIS performance' and 'appropriateness of CHIS design'), **are** supported by the available data from the survey.

Resource availability and allocation

Statistical analyses for the relationship between 'resource availability and allocation', and 'perception of usefulness'; and between 'resource availability and allocation' and 'management commitment to CHIS success' resulted in weak or counter-intuitive cross correlations, although the cross tabulations between these measures were generally positive. The comparison of the rating values for 'resource availability and allocation' for the different CHISs indicated that the system which performed most poorly in terms of most other measures (SystemC) had 71% positive ratings, compared with an average of 33% positive ratings for the Province 1 CHISs (Sys-

temA and SystemB). These statistical analyses therefore were considered in combination with other data related to the conceptual model factor 'resource availability and allocation'.

An important component of the conceptual model factor 'resource availability and allocation' is the availability of the required human resources to support the CHIS implementation at hospital level. The personnel arrangements for information management at hospital level in the two study provinces were rather different: The organogram for posts related to the CHIS at Province 1 hospitals makes provision for Information Officers at each hospital, and a case management function (full- or part time), which includes responsibility for ICD-10 coding for fee-paying patients. For Province 2 hospitals, the organogram includes an information management function at management level, as well as software and hardware support staff. Respondents reported that clinical and/or senior ward administrative staff were responsible for ICD-10 coding. There were no case managers at any of the study hospitals.

Although there were major differences in the organograms in the two provinces, the arrangements for system support appeared to be similar: during office hours, queries were referred to the information officer, a superuser in the section (for example, admissions or fees) or to external personnel responsible for application software or hardware support. After hours, calls were logged at call centres in both provinces, although in some cases, application software support staff were contacted directly. As was found at the case study hospitals, limited CHIS support available at hospital level and from external personnel was not highlighted by most users as a major problem.

Conclusion

Results of this study have shown that the factors of the conceptual model of CHIS use are associated with CHIS success, and that the relationships between factors of the model could be demonstrated.

This study makes a significant contribution to the literature on HIS success and failure on several counts:

- there have been few reported surveys to obtain data on HIS success and failure – data were obtained from approximately 70 users at 30 hospitals, across two provinces, each using one of three CHISs;
- this study was conducted in level 1 and level 2 hospitals using commercially-supplied CHISs, and in environments of limited resources for CHIS support;
- data were obtained from the perspective of CHIS users and hospital managers, rather than from HIS experts as in other reported studies.

Issues to be addressed in future studies include:

- Further refinement of proxy measures for conceptual model factors;
- Obtaining larger and more representative samples of different categories of users, to enable comparison of data from different perspectives;
- Combining data obtained from a CHIS user and user support perspective with data obtained from CHIS experts in the study environment;
- Comparisons between data obtained from public sector level 1 and level 2 hospitals in South Africa with data obtained from similar hospitals in other settings.

The Evolution and Uptake of a Drug Information System: the Case of a Small Canadian Province

Naomi Mensink, Grace Paterson

Medical Informatics, Faculty of Medicine, Dalhousie University, Halifax, Canada

Abstract

In 2008 the province of PEI, Canada implemented a province-wide, web-based drug information system for the purpose of improving patient safety. An evaluation study using grounded theory examined the human and workflow impact. Results indicated a need for great attention to the details of change management during implementation, including: ensuring application quality of all informational and technical elements, just-in-time training and technical support, on-site preparation for changed workflow processes, and collaboration among all stakeholders throughout.

Keywords:

Drug information systems, Cost-benefit analysis, Community pharmacy services, Clinical pharmacy information systems, Drug utilization review

Introduction

Prince Edward Island (PEI), the smallest province in Canada, implemented a system in 2008 for sharing information among pharmacies on prescribing and pharmaceutical dispensing. Implementation of DIS in PEI pharmacies began in March 2008. Following 10 years of planning and preparation in PEI and a ground-swell of national attention to the general process, PEI set a provincial government body in place to create a digital system and network; passed legislation to require compliance; and watched the results unfold. Principles of change management and adoption were actively planned into the process as part of an investment program initiative of Canada Health Infoway [1].

Our study was conducted as a cost-benefit analysis of implementation. The aspects noted in this report are those where we reviewed the results to determine the possible influencing factors around change management that would create differences in efficiency and effectiveness of workflow processes in pharmacies between those which had implemented; those in the process of implementing; and those which had already implemented and become relatively proficient.

Research Objectives

This research initiative was conducted by two members of the faculty of Dalhousie University, at the request of the National e-Pharmacy Task Force. The overall objective was to examine costs and benefits of the Drug Information System (DIS) as it was being implemented so that comparisons could be made among those locations which had already implemented, those that were in the process of implementing and those that had not yet implemented. It encompassed a number of specific objectives. The objective of this paper is to look at the outcomes of the implementation process for three of the objectives of the study and how those can be related to change management processes and uptake of innovations (adoption) that were applied to the implementation process. The three objectives that will be used relate to examining the impact of implementation of the DIS in a) workflow changes; b) acceptance of the DIS by stakeholders, especially practicing pharmacists; and c) observed or recorded patient safety issues including patient education, flags, adverse events and documentation processes [2].

Methods

This study used qualitative methods to gather data for the change management side of the study. Evaluation of costing and the programming was also conducted but is not part of this report. We conducted a review of the history of development and application of the DIS in this province as told by persons directly involved in the process. We observed workflow in 30 of the 43 community pharmacies in the province for at least 1 hour. In each of the pharmacies we prepared sketches of the dispensing area layout and equipment with the physical movement patterns and workflow noted. Following observations, we interviewed community pharmacists (in all instances), pharmacy technicians (in some instances) and with pharmacy managers and/or owners (in a few instances). We held focus groups with pharmacists and managers together. Input from all these sources was then text analyzed and sorted into major themes.

The qualitative research method applied to the objectives of the study was based on grounded theory,[4] or theory generated from the ground up. It explores the social processes of how people interact, take action, and engage in response to a particular phenomenon. In this research, the phenomenon is implementing the DIS in the community pharmacies in a relatively small province that functioned as an excellent living

laboratory. As part of using a grounded theory approach, the researcher guided interviews and focus groups with a series of open questions that were designed to allow the participant to guide the contents of the interview/focus group from that point on. Extensive notes were taken during each interview and focus group, noting direct quotes using the participants' own words. These were shared with the interviewee to ensure that the words and the tone were reflected accurately. Each focus group and interview was preceded by an introduction to the scope and purpose of the research.

The model provided a basis for measurement of factors such as system quality, information quality, service quality, and user satisfaction, which have an impact on benefits realization.

Results

Based on interviews using 30 semi-structured interviews with observations and 2 focus groups, the following common or important themes were brought out by participants:

Table 1-Themes reported by participants

Themes	Frequency of mention in interviews and focus groups
There was near universal commitment by participants to the objectives of DIS: - reduction of medication errors - reduction of drug abuse through double doctoring or poly-pharmacying - prevention of adverse events due to adverse drug interactions	32 or 100%
The province was starting to realize benefits from the DIS	26/32 or 81%
There was a desire for access to the full patient profile and participation by others in the health care system (hospitals, clinics, physicians' offices)	26/32 or 81%
The system generated multiple unimportant alerts that caused concern: - that they may be missing an important alert in the midst of the many unimportant - that it takes precious time to "manage" each unimportant alert, that would better be spent on other things during peak busy times	24/32 or 75%
A perceived lack of collaboration among software providers	
Insufficient preparation for implementation	21/32 or 66%
Need for better clinical information support on drug utilization review (DUR) alerts	5/32 or 16%
Allergy notation related to drug use is too rigid and standards-bound to be useful.	5/32 or 16%
System down-time is a major issue.	27/32 or 84%

The History of the Project around Change Management

Based on several interviews we were able to determine the history of the project. This showed that there was a 10 year period of planning for implementation, with the original ideas for the concept coming from the PEI Pharmacists Association. Between the Association, the government planners, the software developers and the national e-health body there was collaboration on a well-developed change management plan. This included participatory planning by members of the above groups, and support from change management consultants at several levels.

Using Kotter's model of organization development through change management [3], there was an emphasis on such aspects as creating a powerful coalition, that convinced all that change was necessary to the point where legislation was passed to require the change to take place.

There was careful planning around the details of the drug information system software to ensure that all safety issues were adequately addressed. There was a concerted effort to bring all vendors of software that served the individual pharmacies to the table. There was one pharmacy in an urban setting that was designated as a pilot site where the drug information system software was tested and refined.

Commitment to the Change

The findings of the study showed that there was universal commitment on the part of all participants in the process to the objectives of DIS and that the implementation of the system was starting to realize benefits outlined in the objectives, such as improved patient safety in preventing potential drug interactions or duplicate therapies; and recognizing and preventing customers from getting the same prescription filled at multiple pharmacies, as well as preventing customers from using prescriptions for the same medication from multiple doctors. At the point of our study, only community pharmacies were universally expected to be on the Drug Information System, and to share prescribing information across all pharmacies. One major finding was that participants expressed a desire that all stakeholders be on the system, including hospitals, emergency departments, outpatient clinics and all physicians in private practice: that greater benefits could be achieved if that were the case.

Nature of the System for the Purpose

The nature of the system was such that, to be most effective, information on prescriptions for each customer had to be on the system in order to be shared with all other pharmacies. The decision was made to start with no history, so that only new prescriptions were entered on the system. This meant that the usefulness of working with information from the full scope of other pharmacies across the province was not evident in the early days, and that the "costs" in terms of irritation with learning new processes in the middle of a busy work process, was not compensated for, yet, by the "benefits" of being able to see a fuller prescription history for each customer.

From a technology and software programming perspective: observations showed, and participants noted, that there were

multiple unimportant "alerts" (indications of potential patient safety hazards) that were too sensitive. For example, early renewal of a prescription resulted in an alert for "duplicate therapy", or an address that had a different version of a person's name was alerted as an error that had to be corrected before continuing.

Another aspect of the system was that the provincial DIS provided information that was fed into and integrated into the existing pharmacy software that already managed their dispensing processes. For some stores, this made the transition relatively easy, as the learning curve was focused on the information and processes related to the DIS that supplemented their pharmacy software system. In these stores, there might have been some irritation with the multiple alerts, but the transition to using a shared information base was relatively easy and required marginal new learning.

It was discovered that some of these individual pharmacy systems were incompatible with the provincial DIS, so that several groups of stores were required to implement entirely new pharmacy software systems, some of which had lesser functionality than what they had originally. This meant not only a steep learning curve as a totally new software system had to be learned, but also irritation with loss of functions that staff had become accustomed to. This also meant that these pharmacies had to re-enter data about prescribing history in their own stores, which meant a large investment of data entry time. These things had not been planned for in the original change management plan, as it was expected that individual pharmacy software vendors would manage that part of the transition. The researchers heard from participants that there was strong dissatisfaction with the introduction process as a result. This included a perception of insufficient collaboration among the following key stakeholders prior to implementation: the vendor community, the government representatives who were responsible for planning and implementing the DIS, and the DIS system software developer.

Preparation at the Individual Pharmacy Level

One area of importance to participants was a perception of insufficient preparation with the individual pharmacies for introduction of the system in the individual stores. Participants noted lack of on-site training. They noted, and we observed, that pharmacies were very busy places and that there was little time available for training with on-the-job kinds of tools. Since this tool was integral to the primary function of the pharmacy – to dispense medications according to valid prescriptions – and once the system was installed its usefulness was dependent on everyone using it immediately, there was no period of time during which a pharmacist or pharmacy technician could take time away from dispensing medications to learn the new system, because it was the only way available to dispense medications once it was installed. There was no opportunity for parallel systems.

Of the three dispensary software vendors used in the province, we observed only one that sent a training team to work with the dispensary staff to introduce the new system, to enter any background data that was needed, to train staff and to work with them in using the system during the changeover. However, we observed that several of the chains organized for another, we observed that several of the chains organized for an active help desk person from the parent organization, other than the DIS software system team, to be available for sorting out issues. Many participants expressed appreciation for these functions.

Training

There was also a perception of lack of training. In preparation for implementation, the implementation planning group held a teleconference introduction and training session for all pharmacists, that all were required to attend (there was 97% participation). This made it possible for all participating pharmacists to get an introduction to the new processes as well as information on how to resolve issues. The perception of lack of information was thus more likely due to the nature and timing of the teleconference. For many participants, it would have occurred several months prior to implementation, thus any learning from the call would have been lost. For others who may not have been auditory learners, they did not have reinforcing information in other formats to support retention of their learning. As a learning tool, it was likely sadly insufficient to meet the needs. It might have been better to have an on-line support function with help for learning particular processes when the participant actually started to learn how to use the system.

Help and Support

Many noted a lack of information on how to resolve issues and of consistent help desk support from either the provincial DIS provider or from the pharmacy's software provider in the early days. It was not always clear which help function was needed, and participants noted instances where each help desk would suggest that the other would be the better one to call for support.

Discussion

We could find no clearly accepted framework internationally for evaluating the comparative effectiveness of change management processes for eHealth projects [5]. The major model for benefit evaluation in use for Canadian e-health projects through Canada Health Infoway includes user satisfaction and ease of use as a central component of its framework [6]. For purposes of examining the change management process, this study accepts the premise that, for professional healthcare providers (pharmacists and pharmacist/managers), user satisfaction gives an indication of the quality of the system as well as the quality of the implementation process, since their professional interest is in information quality and outcomes for their patients.

Those who have examined the value of an integrated drug information system after its implementation have shown that there is value for prescribing clinicians in having access to a complete drug profile in combination with a clinical decision support system that allows for indications of interactions with other medications in the profile, with health condition or with allergies, and indications of appropriateness of quantities and other factors [7]. A study from an inpatient facility in Taipei [8] that looked at nurses' use of an integrated drug information

system found that it helped to reduce medication errors to a certain extent, except for errors in time of administration. One could speculate that a change management approach that included examining the workflow and perspectives of the nurses might have made a difference to that factor.

Conclusions

There were many valuable lessons to be learned about how to do effective change management around complex system changes to be derived from this study. The principal one appears to be that the process of introduction to users must be as carefully planned in all its details, and prepared for, as the shape of the technology itself. In addition, it seems that the preparations for change must also be focused on each individual workplace or store, since there was significant variation among the ability of each workplace to adopt the changes, and in the perceptions of the store personnel about its effectiveness. Differences included the kind of technology currently in use in the store, and the level of technical expertise of the users. It is the people who are affected most by the change, namely the system users at the interaction point with customers, who are most important. Preparation for the details of the change, support for on-the-spot training, support for technical issues and opportunities to learn in a time and place where the customer will not be affected, are all important aspects that came out in this study.

Social Networking in the National Health Service in England: A Quantitative Analysis of the Online Identities of 152 Primary Care Trusts

Mark D. Hawker

Yorkshire Centre for Health Informatics, Leeds Institute of Health Sciences, Faculty of Medicine and Health, University of Leeds, Leeds LS2 9LJ, UK

Abstract

Increasing numbers of the public are becoming digitally connected. In particular, younger "born digital" generations now use the World Wide Web as their primary source of information alongside conventional media such as television and print. Little is known as to whether health organisations are using new media channels such as Facebook and Twitter to engage with the public and patients. This quantitative analysis investigates the online identities of Primary Care Trusts (PCTs) in the NHS in England to inspect their usage of social utilities. Results showed that a total of 61 organisations (40.13%) use at least one utility with the most popular being Twitter (n=30) and Bebo the least (n=1). However, organisations appear to be failing to take advantage of the interactive nature of social utilities instead using them as unidirectional information "push" channels. The ways in which health organisations could use social utilities for engagement is underexplored and so we must look to other research disciplines for best practice and evidence.

Keywords:

Consumer health informatics, Internet, Organisation-patient relations

Introduction

Five billion minutes are spent on Facebook worldwide per day [1]. In the UK alone, Facebook user numbers account for approximately one quarter (18,711,160) of the population [2]. Collectively Bebo, Facebook, Twitter and YouTube are used by millions of people worldwide to communicate with friends and family, to share and consume information. This is known as online social networking. In healthcare, there could be several use cases for utilising these systems such as facilitating virtual clinician-clinician, clinician-patient and patient-patient interaction. From an organisational perspective, they can be used for internal communication, but also outreach into the community which is the focus of this study. The aim of this research is to quantify whether health organisations in the NHS in England are using these "social utilities" to engage with patients and the public so further research can be conducted into how and whether digital communications is an appropriate communications channel for health organisations.

Primary Care Trusts (PCTs) manage health services such as family doctors, community nursing and dentists, commission secondary care services and account for approximately 80% of the total NHS budget [3]. There are currently 152 PCTs in the NHS in England. Theoretically, they are best positioned to understand the needs of their local communities and work with authorities and other agencies that provide health and social care to ensure the community's needs are met. PCTs are developing "world class" commissioning competencies [4] with the aim of achieving the most cost effective greatest healthcare gain and reducing health care inequalities. One of these competencies is to engage with patients and the public a role now enshrined in the NHS Constitution [5] giving them the right to be involved in the planning, development and feedback of services directly or indirectly affecting their care. Digital communications could form part of this ongoing engagement strategy. We report the outcomes of a quantitative analysis of the online identities of 152 PCTs in the NHS in England.

Methods

To determine whether PCTs in the NHS in England are using digital communications as a means of public engagement, a quantitative analysis of all 152 organisations' digital identities was conducted. Organisation names were extracted from the NHS Connecting for Health Organisation Data Service which provides a downloadable Comma-Separated Value (CSV) or Microsoft Excel (XLS) snapshot of data including national identifiers and local addresses. These names were cross-referenced within the Bebo, Facebook, Twitter and YouTube social utilities to assess whether the organisation was represented. If an organisational presence was found it was investigated using metrics defined for each social utility. A preliminary search was conducted to identify that these four social utilities were being used by the NHS organisations and ruled out other social utilities such as MySpace as no accounts were found. In the future it is possible that other social utilities will be adopted and current metrics will need to be created to include them.

Founded in January 2005, Bebo ("Blog early, blog often") is a social networking site similar to Facebook. It allows users to share video, photos and groups as well as providing blog and whiteboard commenting functionalities to communicate and

share with friends. Bebo profiles list the number of times somebody visits a profile and also public information that has been permitted to be shared including the number of friends a user has. As suitable metrics the number of videos, photos, groups, blog posts, whiteboard entries, comments, number of friends, profiles views and links back to Facebook, Twitter and YouTube were recorded.

Founded in February 2004, Facebook is the largest and most-used social utility in the world today [6]. While complex, Facebook gives users full control over their use of core applications such as Photos, Groups and Video. The context analysis was split into three Facebook entities:

- Facebook Profiles are reserved for individuals and are not generally accessible to the public due to privacy restrictions. For this study they were excluded as there was no way of verifying whether they are owned by the official organisation.
- Facebook Groups can be created by anybody and are generally used for petitions, tributes and general conversation. Closed or "secret" groups are available which require an explicit invite as public ones can be subject to exploitation by malicious users.
- Facebook Pages are reserved for organisations and other business entities rather than them creating an individual account which is against Facebook Terms of Use. Facebook Pages are like Groups but are more flexible in terms of functionality and control.

All entities were queried using the internal Facebook search engine although Profiles were excluded from the quantitative analysis. As suitable metrics the number of members (fans), discussion topics and posts, notes (only on Pages), wall posts (only on Groups), photos, links, videos, events and links back to Bebo, Twitter and YouTube were recorded. Only "official" Groups were analysed which were filtered by discounting ones which did not display a legitimate .nhs.uk e-mail address. This is not a perfect solution but an adequate indicator of veracity.

Founded in 2006, Twitter is an open social networking and micro-blogging service that enables its users to send and read messages known as tweets. Like a cocktail party, users amass in groups and talk openly whilst listening in to surrounding conversations and contribute if they hear something interesting. On Twitter users "follow" others so that their tweets appear in their tweet-stream (the conversation) and can also be "followed" by other users so that they appear in somebody else's tweet-stream. As suitable metrics the number of tweets, following, followers, date joined and links back to Bebo, Facebook and YouTube were recorded.

Founded in February 2005 YouTube is a video-sharing site owned by Google, Inc. YouTube allows users to share, upload and comment on videos worldwide through playlists and user accounts known as "channels". Many YouTube videos are made public and are easily accessible which has both positive effects on mass viral distribution and reducing barriers to entry for video clip and movie producers but also brings negative effects such as comment abuse and illegal uploading of copyrighted materials. As suitable metrics the number of channel subscriptions, videos, channel views, date joined and links back to Bebo, Facebook and Twitter were recorded.

Data was collected on the 29th July, 2009, using a tripartite search strategy: via four generic Google search queries e.g. *NHS OR PCT OR "Primary Care Trust" site:bebo.com* replacing *bebo.com* with *facebook.com*, *twitter.com* and *youtube.com* to identify presences across the WWW; an internal Facebook search for *NHS OR PCT or "Primary Care Trust"* to identify Facebook Groups and Facebook Pages; and, PCT-specific Google searches e.g. *bebo OR twitter OR facebook OR youtube site:doncasterpct.nhs.uk* for all 152 organisations to identify any missed presences from the previous searches. Each presence was investigated and quantitative data recorded for each metric. Due to the human element of inquiry and the need to assess veracity this process was not computer-automated. Results were stored in Microsoft Access and exported to Microsoft Excel for analysis. Each result was then marked with the date it was collected to allow for future longitudinal research.

Results

Figure 1 shows the total number of online accounts (Bebo, Facebook, Twitter and YouTube) created by PCTs in the NHS in England. In two instances, two PCTs had two Facebook Pages which were both included in the data analysis. The results show that Twitter is the most widely adopted platform (n=30) although this represents only 19.74% of total organisations, and the least adopted platform is Bebo (n=1). While Figure 1 gives an indication of quantity it does not give any indication of qualitative engagement by the public and patients.

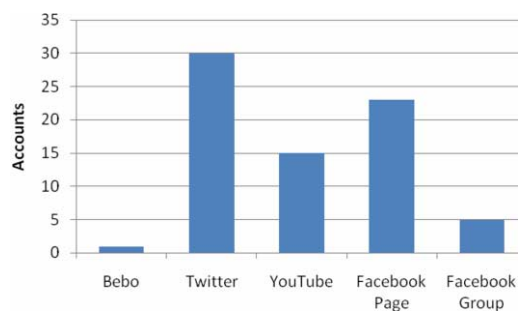

Figure 1 – Total Number of Accounts (n=73)

The total number of accounts represented 61 organisations (40.13%) out of all PCTs. Out of these organisations 42 (68.85%) utilised a single social utility, 16 (26.23%) used two, and three (4.92%) used three utilities. From the collection of official PCT web sites only three linked to their Facebook Group or Facebook Page, 12 to their Twitter accounts and four to their YouTube account. These statistics suggest that no clear, unified strategy has been enforced to link all identities or to align with organisational and communication strategies

which could lead to a richer, more streamlined experience for patients and the public.

Bebo

Only one organisation was utilizing the Bebo social utility. This organisation utilised all parts of the platform – photos, blog posts, videos, groups, comments and whiteboard – and had 136 friends and 76 profile views. Due to the low uptake of Bebo it is questionable whether it is a suitable utility for public engagement. Further investigation is required to elicit why the organisation decided upon Bebo and what prior market research led them to adopt the platform.

Facebook

Table 1 shows the frequencies of metrics across five Facebook Groups and 23 Facebook Pages which account for distinct 28 organisations. In one instance two organisations were amalgamated as they were using the same Facebook Page. Two organisations had two Facebook Pages which were both included separately. The results show many organisations failed to engage at all, with zero metrics accounting for 61.11% of outcomes. While discussions were used in 13 (44.83%) cases, in only five (38.46%) was a reply to the original post made. In only three cases did the organisation reference their presence on another social utility – all were Twitter.

Table 1 – Facebook Engagement (n=28)

Metric	0	1	2-10	11-20	21+
Discussion Topics	17	6	5	0	0
Discussion Posts	17	4	7	0	0
Events	19	5	4	0	0
Members (Fans)	3	2	9	3	11
Links	15	3	7	1	2
Photos	19	2	5	0	2
Notes	14	2	6	1	0
Videos	21	4	3	0	0
Wall Posts	2	1	2	0	0

To better understand engagement strategies, means were calculated to determine how often these strategies were employed across each organisation. Organisations provided more links (m=4.000, SD=9.623) than any other strategy, but also posted notes (m=2.217, SD=3.884), photos (m=1.786, SD=6.711) and discussion posts (m=1.107, SD=1.892). For discussions it is important to note that of the 11 organisations that used them, only 5 (45.45%) had a reply to an original post. The mean number of members (fans) was 35 (SD=58.421) with support varying from a high of 277 to a low of zero.

Twitter and YouTube

Figure 2 shows the cumulative number of organisations on Twitter and YouTube since June, 2007. In one instance two organisations were represented via a single Twitter account and so only one instance is reported. Since the beginning of January 2009, which was when Twitter began being mentioned in mainstream media, there has been a sharp increase in the number of Twitter accounts opened, and a marked plateau of account openings on YouTube. Further longitudinal research will need to be conducted to identify whether this trend will continue to be satisfied or whether it will plateau like YouTube in the future.

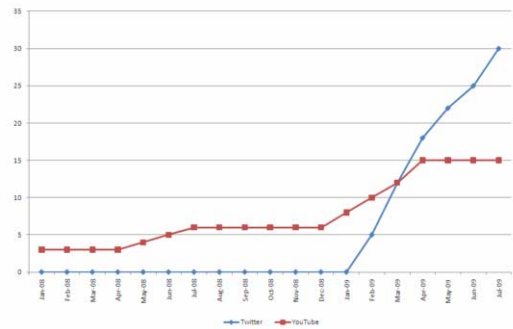

Figure 2 –Accounts Opened on Twitter (n=30) and YouTube (n=15) Since June, 2007

Figure 3 shows a bubble chart of the relationships between subscriptions, videos and channel views (indicated by the bubble size) of all 15 YouTube accounts.

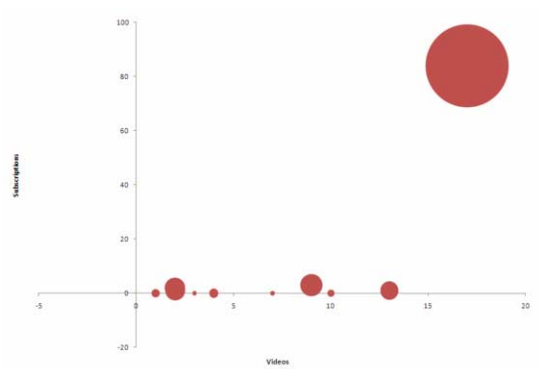

Figure 3 –YouTube Engagement (n=15)

The correlation between metrics is positive with subscriptions to channel views being the strongest (0.9982) followed by videos to channel views (0.6857) and videos to subscriptions (0.6764). This suggests it is more about the quality of videos to gain channel subscriptions than posting multiple videos that are not engaging. The large value in the top-right of the chart was due to a controversial video related to teen pregnancy which generated lots of media attention and thus increased views of the video before it was removed.

Discussion

By analysing the amount of content of online identities of PCTs in the NHS in England this study found that organisations using social utilities were in the minority. The tentative use of technologies parallels earlier studies on how public relations practitioners viewed the WWW and its impact on relationship building. Hill and White [7] found even though the value of the WWW for helping improve an organisation's competitiveness and image was recognised, they were sceptical about its ability to advance. Practitioners highlighted that they "could not articulate or demonstrate with research that they were currently achieving [these] benefits" and that often their sites "did not reflect positively on the organisation". Even though this research pre-dated utilities such as Facebook and Twitter there is still a reluctance to adopt online identities.

This research fits within the broader context of consumer health informatics (CHI) which is defined as "the branch of medical informatics that analyses consumers' needs for information; studies and implements methods of making information accessible to consumers; and models and integrates consumers' preferences into medical information systems" [8]. CHI focuses on prevention, self-care, patient empowerment and "consumer-as-partner" models of care rather than traditional, industrial-age, paternalistic, educational or Internet-age models of the consumer-professional relationship [9]. A subset of CHI, Medicine 2.0, describes an eHealth development which defines the broad adoption of Web 2.0 technologies and approaches to social networking, participation, apomediation, openness and collaboration within and between numerous stakeholders of health and social care [10]. This paper describes one element of a much broader picture and focuses on the interaction between healthcare organisations and the public using social networking. As an increasing number of "born digital" generations are entering the world of work their expectations of openness, transparency, access and privacy vary greatly from their predecessors. It could be hypothesised that these Generation Y (and beyond) workers could be the change agents required in healthcare technology utilisation [11] such as their ubiquitous use of the social utilities in their personal lives.

Our results indicated that organisations are failing to take advantage of the interactive nature of social utilities instead using them as unidirectional information "push" channels for news and links and providing a contact e-mail address instead of embracing components such as tweets and wall posts. It is unknown whether this is a strategic decision or one related to lack of operational knowledge as few guides exist for organisations on how to use these sites. Official Twitter [12] and Government [13] templates are emerging to fill this gap but what is not known is how they apply to health organisations and whether they need to be adapted to suit stakeholder groups. In health there is often a reluctance to engage with open systems for fear of reprimand or breaches of confidentiality. The fact that the Government appears to be endorsing the systems may be at odds with other controls within the service. Further research is needed into how these documents can be disseminated, used and evaluated across organisations.

The ways in which health organisations could use social utilities is underexplored and so we must look to other research disciplines for evidence. An analysis of non-profit organisations' use of Facebook for stakeholder engagement [14] suggested it could be used for message dissemination such as posting links to external news items about the organisation such as press releases or its campaigns and causes; posting photographs, video or audio files from the organisation and its supporters; and using discussion boards to post announcements and answer questions [15]. A calendar of events or listing volunteer opportunities was encouraged to bolster offline communications. Putting the influence research of Watts and Dodds [16] into practice who concluded that "large cascades of influence are driven not by influentials but by a critical mass of easily influence individuals" would suggest that by increasing the number of communications channels used you will increase the serendipity of these random information cascades. However, this was noted as being outside of the scope of the research paper. Would creating a Facebook Event or using targeting social advertising recruit more people to patient engagement focus groups?

Outside of academe there are two public projects that show that this is not just topical in the UK. Ed Bennett, a Hospital Web Manager from the United States has compiled a "Hospital Social Network List" of 351 organisations using Blogs, Facebook, Twitter and YouTube which is updated on a regular basis [17] and complementary to this, Lucien Engelen has begun compiling a "European Hospitals List" [18]. Preliminary results show that a staggering 253 (72.08%) of American hospitals have a Twitter account and approximately 50% have Facebook and YouTube accounts. Is this purely down to the competitive nature of care in the United States? Or is it something more complex?

Maintaining a digital identity will not in itself increase awareness or engagement as links between any two people do not imply an interaction between them as was shown by an analysis of a sample of Twitter users [19]. With an appropriate strategy, leadership, policy and guidance there is no reason why more health organisations cannot sensibly embrace new technologies rather than their adoption being linked to one or two keen enthusiasts who use them for personal use. What this research contributes is that organisations are using online identities, whether rightly or wrongly, and from those that do not digitally engage we can investigate whether this is an informed decision or ignorance.

A limitation of the data collection process was assuring veracity of digital identities. Veracity was assessed by the presence of an official NHS contact e-mail address or list of administrators that belonged to the organisation. Where appropriate, identities that appeared unofficial due to spurious e-mail addresses or objectionable content were removed and the organisations were contacted regarding the offending and potentially damaging presence. In all cases, there was no perfect and scalable way to address trust issues but this reflects the un-monitored nature of the World Wide Web (WWW). Further research involving organisational stakeholders is needed to address this issue. What is still not known is the effectiveness of engagement on social utilities such as Facebook and Twitter as little health-focused research has been

published to address this. Social utilities may have been adopted purely to "ride the wave" rather than forming any part of a much wider organisational communications strategy. Whether or not this is true was not the rationale behind this research, but to state that this is happening whether authorised or not.

Conclusion

The quantitative analysis has proved that the adoption of technologies such as Bebo, Facebook, Twitter and YouTube in PCTs in the NHS in England is underway. We identified that Twitter was the most popular and fastest-growing social utility although this was closely followed by Facebook and YouTube. In all cases there was no apparent strategy to integrate all information channels although this may not have been made available to the public. Further research is needed to qualify this hypothesis and to gain feedback from those organisations that are both using and not using these technologies. We must explore each social utility in detail to identify why they are being used, evaluate how effective they are and what values organisations perceive they have so that others can see the benefits or drawbacks of digital engagement. Longitudinal studies could offer insights into how organisational strategies change over time and case studies should be conducted both in the UK and other countries as a means of sharing successes and failures of engagement efforts.

Standardizing Implementation of a Surgical Information System in Danish Hospitals – A Comparative Study

Kitta Lawton[a], Marianne Holdt[b], Pia Kopke[c], Hrönn Sigurðardóttir[d]

[a] *Project Department, Corporate IT, Capital Region of Denmark* [b]*Customer Relations, Corporate IT, Capital Region of Denmark*
[c]*Customer Relations, Corporate IT, Capital Region of Denmark* [d]*PhD fellow, IT University of Copenhagen*

Abstract

Implementation of IT-systems in modern healthcare organizations is associated with large, complex, and expensive projects. Purchase of the system is costly, but resources used to implement the organizational changes that follow, can be extensive. In an attempt to reduce costs, and at the same time to provide a thorough basis for local implementation, Corporate IT in The Capital Region of Denmark developed a standardized system-specific implementation concept for use by the hospitals´ local implementations of a Surgical Information system. The system has been implemented in five hospitals within the Capital Region. Through document analysis and interviews with the local project managers, we investigated the use and effectiveness of the standardized implementation concept across five hospitals involved. The study shows that total resource requirements and duration of projects are difficult to compare due to different constructions of the project organizations. We conclude that the implementation concept supports local IT-implementations, but parts of the concept are difficult to translate into practice, while other parts are directly operational.

Keywords:

Standardization, Implementation, Surgical information system, Organizational innovation, Change management

Introduction

Implementing new IT-systems is an activity which modern healthcare organizations have to manage alongside day-to-day operational tasks. These implementation projects are often large, complex and expensive, since they include not only costs related to the purchase of the IT-system, but also resources concerning the associated organizational changes that are required. A detailed plan that is driven by both capacity for change and context of change [1] is required, which includes change management, training, workflow analysis, and configuration of the IT-system [2].

One way to control IT implementation costs in large organizations is to standardize the implementation process. However, such a top-down approach can be problematic when viewed from a sociotechnical perspective, which argues that the specificities of the local work practices are essential and need to be taken into account for the setup and use of a new information system [3]. In an attempt to standardize the implementation processes and thereby reduce costs, while simultaneously facilitating the local adoption of the IT system, Corporate IT in the Capital Region of Denmark developed a Standardized System-Specific Implementation Concept (SSSIC) for use in the local implementation of a Surgical Information system in the Region´s thirteen hospitals. Development of the SSSIC is based on recommendations from selected literature on implementation [4], which divides implementation into five key activities: communication, workflow analysis, project organization, education, and configuration.

The Capital Region of Denmark has 36,000 employees and is responsible for providing healthcare to the region's 1.6 million inhabitants. Corporate IT is responsible for IT acquisition, maintenance and operations. The local hospitals and their IT-organizations are responsible for implementing new IT systems in the hospital wards. The typical lifecycle of IT-projects in the Capital Region is as follows: Corporate IT is responsible for the acquisition of the system; this phase of the project includes two pilot projects that involve the clinical utilization of the system in two different hospital wards. The aim of the pilot projects is to validate the suitability of the system in real-life work situations, as well as to estimate change requirements and training needs. An impact evaluation of the system is also performed in the pilot projects.

After completion of the two pilot projects, the project manager from Corporate IT and the local project manager in the pilot hospital produce a report that documents experiences gained during conducting the pilot projects. This documentation forms the basis of the SSSIC, which consists of guidelines and templates for use in the different implementation activities such as project organization, workflow analysis, education, configuration and communication. During a collaborative workshop, the SSSIC is presented to the local project managers from the hospitals which are due to implement the system. An overview of the SSSIC is presented in Figure 1 below.

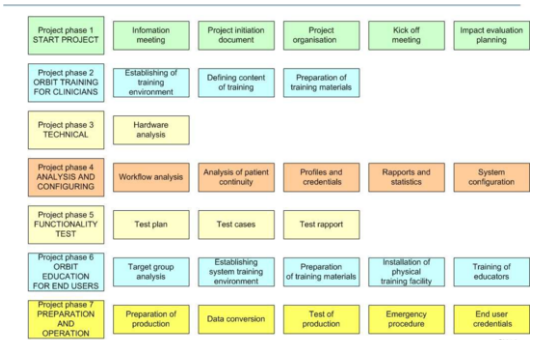

Figure 1- Overview of the Standardized System-Specific Implementation Concept

The first SSSIC was produced in relation to the ORBIT pilot project (OpeRation planning By Intelligent Technology). The purpose of providing the standardized implementation concept to the hospitals is primarily to simplify the implementation process and reduce time consumption for each of the hospitals and thereby reduce cost. Furthermore, the objective is to provide a point of departure for the local implementation projects, identify better practices, and to prevent repetition of mistakes that occur during the pilot projects.

ORBIT is a standardized surgical information system used for planning and documentation of surgical procedures in surgical departments. In addition, ORBIT is based on templates that are configurable by each surgical ward [5]. The system helps to secure effective use of resources needed for each surgical procedure e.g. the operating theatres and manning [6]. The clinicians' real-time documentation provides a constantly updated view of planned, on-going, and completed surgeries. Furthermore, ORBIT provides a graphical overview of the surgical schedule, which is available from multiple locations in each department and allows the ward staff to follow the actual status of ongoing surgeries.

By the end of 2009, ORBIT will be implemented by nine out of thirteen hospitals within the Capital Region and used by 16.000 clinicians. At the time of our study, the system had been implemented in a total of five hospitals. This paper investigates the implementation of ORBIT across these five hospitals with focus on the use and effectiveness of the SSSIC. The structure of the paper is as follows. First, we introduce the methods utilized for data collection and analysis. Second, we present the results of our study. Third, we discuss the findings in relation to the overall aim of the study, and finally, we conclude on the use and effectiveness of the SSSIC.

Materials and Methods

In order to assess the ways in which the SSSIC supports implementation, we conducted a study in early spring 2009, including local projects and their respective project managers in the five hospitals. This comparative study is a simple approach used to extract quantitative and qualitative data concerning the implementation activities [7]. Through document review, we identified and compared similarities and differences related to time utilization and costs in each of the respective projects. Furthermore, we aimed to elaborate on areas of special interest, importance, and unforeseen discoveries. The study focuses on the elements contained in the SSSIC and on the general use of implementation activities. To understand the scale of each project, we extracted quantitative data from local project documentation from each implementation activity in order to objectively compare time and resource consumption in detail.

On the basis of the listed activities in the projects documentation, we developed a semi-structured interview guide to provide direction with regards to the interviews with the project managers of the local implementation projects. Each semi-structured interview guide was further refined with the quantitative data from the document review [8]. The project managers received the interview guide a week prior to the interview in order to validate the questions and to prepare them regarding the issues we wished to discuss. Furthermore, we interviewed the project manager from the Corporate IT pilot project and the Coordinating System Administrator (CSA) who is also employed by Corporate IT.

The aim of the interviews was to validate and elaborate on the information extracted in the document review according to the actual performed implementation activities and use of resources. The interviews enabled us to identify and elaborate on issues unique to the specific hospital and project activities that were carried out differently than stated in the project documentation. We transcribed all interviews, and for analysis we thematized the data according to the elements in the SSSIC, condensed, and construed meaning.

Results

The results from our study are structured according to the listed implementation activities in the SSSIC with focus on similarities and differences between the hospitals. However, the data extracted from the quantitative analysis proved impracticable to compare, due to profound differences in the organization of the local projects and variation in the recording of documentation.

Across the five hospitals, we found great variation in how the local projects were *organized*. This influenced not only the manner in which cost of resources utilized and project duration were documented, but it also affected the duration of the project. In order to optimize new work processes in ORBIT, one hospital decided to introduce Lean as a parallel project with shared resources. Another hospital shared the Executive Group and the administrative tasks with two other projects. In two hospitals, ORBIT was introduced to all of its surgical wards as one, single, all encompassing implementation project. The other three hospitals conducted the project as a sequence of smaller sub-projects with each of the individual surgical ward following one other consecutively. Influenced by the manner in which the local projects were organized, the duration of implementation varied from 32 to 85 weeks across the five hospitals. Ensuring sufficient resource allocation for the im-

plementation project as proposed in the SSSIC, proved a significant challenge for two of the local implementation project managers. The project manager of the pilot project and the CSA acknowledged this challenge, and expressed frustration due to lack of authority regarding the resource availability.

All five project managers emphasized the importance of *communication*; that communication to managerial level, as well as to general staff, is important for consolidating the project in the organization. However, only three of five hospitals had an actual written communication strategy in their project plans, and none of these were in accordance with the guidelines provided by the SSSIC. None of these three hospitals kept to their plans regarding communication to end-users and surrounding context. Furthermore, communication activities were down scaled as soon as concrete operational activities pressed the project. In all five hospitals, the clinical managers were responsible for distributing information about implementation to hospital staff, and in two of the hospitals, the project managers followed-up on this task. The project manager of the pilot projects found it challenging to stress the importance of communication enough in the SSSIC.

The third element we compared was *workflow analysis*, which is used as basis for configuration of ORBIT. An external specialist consultant developed the method proposed in the SSSIC for analyzing workflows. Three of the five hospitals used the consultant to analyze the workflows in their wards. One project manager was critical to the fact that the workflow analysis was confined to only one of the initial phases of the project. She argued that the analysis should be iterative, as it is her experience that project members gain valuable knowledge throughout the entire project. Another project manager was not aware of the importance of introducing the participants to ORBIT before the workflow analysis. As a consequence, several dilemmas surfaced as it became clear that the outlined new workflows were not aligned with the possibilities provided in ORBIT. The project manager in the fifth hospital did not use the recommended method, but chose to observe and interview ward staff as basis for the workflow analysis. Although four of five projects used the method suggested in the SSSIC, local resources in only one of the projects performed the task. The project manager in the pilot project stressed that the method presented in the implementation concept is merely a guideline, including templates, which can be altered or substituted according to local needs.

The fourth element in our analysis is *education.* Training in ORBIT is twofold; a thorough training of the clinicians who partake in the implementation project in order to equip them to configure the system to the needs of the department. And end-user training for ward staff, adapted to the system tasks specific for each profession. An external consultant, who for the most part also produced the training material during the pilot project, performed the training for the project participants in system configuration. In addition, one of the hospitals used the same consultant to facilitate the training of end-users. The training of the staff in the other four hospitals was conducted either by the IT-department or the clinical project members in the ward. The training material produced in the pilot projects and published in the SSSIC had been adapted and used in all five hospitals. In addition, one hospital produced a small educational video as a supplement to the SSSIC.

Configuration is the fifth element of our analysis. System configuration is a comprehensive activity in the implementation of ORBIT. The system must be configured according to the outcome of the workflow analysis (e.g. set up to support the local work practices in each individual ward). First, a test version of the system is installed to run tests according to workflow. Then, the configuration is repeated in the production version of the system including any necessary changes. Optimally clinicians perform this work as it involves items of clinical documentation. Due to pressure in maintaining schedule in the ward, the project manager in one hospital configured the system despite project contracts with clinicians. Consequently, the hospital decided that the future configuration was to be performed by IT-staff. The clinicians configured the system in the other four hospitals, with the support of the project manager.

None of the five project managers used the SSSIC to its full extent, although the training material was widely used. Four of the project managers possessed vast knowledge of the content of the material and the scale of implementation in ORBIT, so they merely used the material as reference and to some extent substituted some of the proposed standardized methods with others. When implementation at the fifth hospital was started, the material had not yet been distributed, but to accommodate this, the pilot project manager from Corporate IT assisted in drafting the project plans for the hospital and accessing the undistributed material. The local project manager with no prior experience in implementing ORBIT, kept close to guidelines, methods and templates recommended by Corporate IT, and did not exhibit the same autonomy as the project managers with prior hands-on experience.

All five project managers found the material useful, but all expressed that a complex implementation project, such as ORBIT, cannot fully rely on written material as distributed in the SSSIC. They shared the opinion that greater use could be made of the coordinating system administrator (CSA) in supporting the local projects at the outset as well as being the carrier of experience between the hospitals. However, they believed that a distributed pack of materials would be adequate for less complex projects.

The Corporate IT project manager involved in the pilot projects, as well as the CSA agreed on this point of view. They strongly suggested involving the CSA as early as possible in the pilot projects, preferably in the test phase in order to gain a thorough knowledge of the system, which (s)he will be administrating. Thus, for projects as complex as ORBIT, they suggested a taskforce to be formed in order to collect and share experience between the hospitals, and to provide assistance in the early stages of the local projects. One of the experiences obtained over time is that the local project managers request implementation concepts for new projects to a greater extent. On these grounds the project manager in the pilot expressed a wish for a much stronger collaborative effort between the hospitals in the production and maintenance of the individual parts of the SSSIC. For example, when a local project substi-

tutes a method with another, elaborates, changes or extends material, they should publish guidelines, templates, and results for use in the other hospitals.

Discussion

The present study examined the use of a Standardized System-Specific Implementation Concept (SSSIC) for use in implementation of a complex IT-system in five Danish hospitals. Due to variation in the organizational construction of the five local projects, the study rendered it impossible to extract comparable objective values for *use of resources* and *project duration* and thereby costs. As a consequence, we omitted the planned comparison of costs and duration of implementation. Furthermore, the study shows that compliance and utilization of guidelines and templates provided by the concept varied across the five hospitals and was primarily related to the local project managers' prior knowledge of the pilot projects. This suggests that both thorough knowledge of the local context and understanding of the technology which are to be introduced, are critical skills for the project manager. This is supported by Lorenzi and Riley who found, that failure to succeed in implementation can be outlined in four major categories: technical shortcomings, project management shortcomings, organizational issues, and the continuing information explosion [2].

Communication is essential to change management, especially managers taking responsibility for change. The clinical management was responsible for end-user communication activities in all five implementation projects. However, the study showed that the concrete tasks in the project and the daily clinical practice often lead to a downgrading of planned communication activities. The organization requires a change owner who constantly demands the implementation of the change [2], and failure to do so, poses a great risk for resistance to the project. For all of the local projects, the IT departments inhabited the role of change owner, performed by the local project manager. For all of the five projects, the local project managers communicated on a regular basis with the Executive Group and clinical managers, but delegated the task of end-user communication to the clinical management. For three of the hospitals, this left the change owner out of touch with the actual level of information provided to the end-users. In two hospitals where the project managers followed up on communication, they were able to instigate further activities for change management.

Most of the local project managers were unable to conduct *workflow analysis* based on the guidelines and template provided in the SSSIC, and three out of five hospitals hired a consultant to perform this task. Workflow analysis is an essential activity when implementing IT systems in clinical wards, but the form and content of the analysis vary widely and depend on the participants and the purpose of the IT system; i.e. Business Process Reengineering (BPR) [9], Use Cases [10], or Computer Supported Cooperative Work (CSCW) [11] is often used. The challenges with workflow analysis are many; including the users' expectations of the IT system being tailored to their workflows and not vice versa. Such a desire can be problematic when implementing standard systems like ORBIT. In addition, it is questionable to what extent it is possible to model clinical workflows, characterized by numerous interruptions and complex decision making [12]. However, for ORBIT projects, workflow analysis is performed in order to enable clinicians to configure the system to best fit local practices. Thus, the need to hire an external consultant to perform the analysis, suggests that the local project managers were not confident in performing the task even with the method presented. The complexity of the method, the managers lack of prior experience of performing a workflow analysis, and for one of the project managers; lack of understanding of how in fact, the result should be brought into effect, are all possible reasons the project managers did not perform the workflow analysis independently supported by the method presented in the SSSIC material.

Thorough *education* of the clinical project members roots the project in the ward; it also transfers the responsibility for system maintenance from the IT-staff to the ward staff, which has the local knowledge needed for configuration and thereby to render a successful implementation possible [13]. The training material and tools included in the SSSIC were used extensively, suggesting that this part of the concept is easier to reuse across the organization. The core functionality of the system is the same and the local project managers can, with few resources, customize the training material to local practice. Nevertheless, one hospital supplemented the existing teaching methods with an educational video. This finding suggests the need for a broader range of training methods to accommodate the different needs for IT training among clinicians.

As ORBIT requires *configuration* according to local practices, it is essential for the quality of the future workflows and surgical documentation that the clinicians configure the system. For all five hospitals, contracts for devoting clinical resources to the projects were agreed upon. However, as the organization failed to substitute resources, the pressure of surgical schedules pressed the projects, as clinicians' commitment is primarily to their clinical work. Characteristic for all the hospitals is that the IT department holds ownership of the project through configuration and system maintenance. The advantages of ownership by clinicians are that it roots ownership of the system and system knowledge on location as argued by Pries-Heje et al. who state that ownership held by the ward secures the clinicians' commitment to the project and subsequent use of the system [14].

The SSSIC proved useful as a reference for methods and plans for implementing the specific system, and four out of five project managers exhibited great independence as how to put it into use based on their prior knowledge of the methods and the system. Only in the case of training material did the project managers kept very close to material and guidelines from the SSSIC, which also proves to be a most time consuming activity. However, as one hospital chose to produce a supplementing educational video, it is worth considering a broader selection of educational material for future projects.

The SSSIC for ORBIT was the first of its sort in the Capital Region of Denmark, and for this particular project, the local system implementation projects proved to be unable to rely on

written material alone. The complexity of the system implementation is one reason, but also differences in organizational constructions according to local culture played a role. However, as the local project managers presently request SSSIC for new projects, we reason that although a standardization of the implementation processes did not occur, the study showed that standardization of the implementation documents, methods and guidelines, establishes a framework of best practice from which the local projects draw valuable information and material. Furthermore, an earlier and deeper involvement of the CSA would be a valuable carrier of knowledge across the hospitals.

Conclusion

The standardized system-specific implementation concept (SSSIC) has not led to the standardization of the implementation process but contributes to the efficiency in the project through references to methods, and especially through the reuse of training materials. The SSSIC must be designed according to the complexity of the system implementation and the experience of the project managers. However, at the same time, it must be possible for the project managers to customize the content to accommodate local practices. The study exposed the varied ways in which the different local projects planned and performed the implementation of ORBIT. This influenced the possibility of comparing project duration and expenses.

For implementation projects as complex as ORBIT, the project managers request the CSA to play a larger role from an early stage of the project, in order to share and distribute experience between the hospitals.

Acknowledgements

We thank the local project managers for taking the time to be interviewed and for granting access to the project documentation necessay for our analysis.

Interoperability prototype between hospitals and general practitioners in Switzerland

Abstract

Interoperability in data exchange has the potential to improve the care processes and decrease costs of the health care system. Many countries have related eHealth initiatives in preparation or already implemented. In this area, Switzerland has yet to catch up. Its health system is fragmented, because of the federated nature of cantons. It is thus more difficult to coordinate efforts between the existing healthcare actors. In the Medicoordination project a pragmatic approach was selected: integrating several partners in healthcare on a regional scale in French speaking Switzerland. In parallel with the Swiss eHealth strategy, currently being elaborated by the Swiss confederation, particularly medium-sized hospitals and general practitioners were targeted in Medicoordination to implement concrete scenarios of information exchange between hospitals and general practitioners with a high added value. In this paper we focus our attention on a prototype implementation of one chosen scenario: the discharge summary. Although simple in concept, exchanging release letters shows small, hidden difficulties due to the multi-partner nature of the project. The added value of such a prototype is potentially high and it is now important to show that interoperability can work in practice.

Keywords:

Hospital information Systems, Medical informatics, Medical records, Interoperability.

Introduction

The advent of fully electronic patient records has strongly altered data management and processes in hospitals [1]. The availability of all data in digital format allows for an easy communication and clinicians can access the records at the same time as data can be duplicated easily. The exchange of health data in digital format also has other advantages because data loss can be prevented (for example compared to the case of images transported on film) and it can lead to the availability of essential and more complete data on patients avoiding mistreatments [2,3]. Double examinations can be avoided if the examination results can be communicated quickly.

To tackle the high potential of the domain of medical interoperability but also respond to potential risks of data abuse, strategies for the interoperability exist in many countries [4,5] and also on a European level [6]. The Swiss Confederation has also started an eHealth strategy creating a clear outline for the next ten years of managing health data at various scales, and including participants from a large number of interest groups. This effort has lead to several concrete propositions for potential standards regarding data exchange and particularly an identification of partners in the system. For a highly federated country such as Switzerland a strongly distributed structure is foreseen, storing the data at the place where they were produced, and then allowing selected access.

Although many standards already exist in the domain, not all of them offer an optimal scenario and the choice needs to be made well as the consequences are important. HL7 CDA (Health Level 7, Clinical Document Architecture) offers formats for exchanging several types of documents and CEN 13606 (European Committee for Standardization) also offers a general framework for data exchange. Coding standards exist for many domains including ICD (International Code of Diseases) for diseases, SNOMED CT (Systemized Nomenclature in Medicine Clinical Terms, [7]) as a very large-scale terminology, LOINC (Logical Observation Identifiers Names and Codes) for laboratory and clinical results, and many others.

Political processes usually advance slowly as it is a sensitive domain and wrong steps can lead to negative feedback, particularly for politicians interested in the voter's opinions. On the other hand a clear need is currently visible to have all health data of a patient in a single place. Large companies such as Microsoft[1] and Google[2] have also realized this and allow for a creation of personal health profiles. In the US many hospitals also offer such personal health records or allow for an export of the data to one of the commercial solutions [8]. This creates a risk that the commercial players might misuse the data they manage. On the other hand, patients have an interest to have a complete personal health profile.

The Medicoordination[3] project described in this paper tries to complement the Swiss eHealth strategy by collaborating mainly with regional medium-sized hospitals and smaller partners in the health system, where data exchange has not been an as important subject as in large University hospitals that often already exchange health data with external actors [9]. By communicating with several actors in the health system, a few scenarios for health data exchange could be identified, where a simple implementation brings a clear added value for all part-

[2] http://www.google.com/health/
[3] http://www.medicoordination.ch/

ners. This allows for testing the infrastructures in parallel to the creation of the eHealth strategy also for smaller actors in the health system to gain experience with these tools and potential problem. This project has currently limited its scope to the French-speaking part of Switzerland.

This paper presents the prototype implementation of an interoperable healthcare infrastructure. The MediCoordination Healthcare Infrastructure (MHI) is based on the recommendations of the Swiss Confederation [5] and is intended to make accessing and sharing important medical data between small-to-medium medical actors more efficient and easier. The objective of the project is to promote electronic healthcare data exchange Switzerland, through:

- the adoption of technologies recommended by the Swiss Confederation, especially Integrating the Health Enterprise[4] (IHE);
- an informative survey, representing the interoperability requirements of the Swiss medical industry;
- a prototype emphasizing the benefits of interoperability in the context of electronic data exchange.

The goal of the prototype is to communicate a release letter from a hospital to a general practitioner (GP) identified by its EAN[5] (European Article Number) number in an automated way, and integrating the letter directly into the GP health record without manual intervention. The prototype is fully implemented and deployed. Its design, implementation and tests are presented in this paper.

Methods

The Medicoordination project includes two distinct phases. During the first phase interviews were performed with several actors in the Swiss health sector (limited to the French-speaking part of Switzerland), from small to medium and large hospitals, medical associations, insurance companies, producers of laboratory and imaging data, producers of software for GPs and hospitals. The selection was made after creating an exhaustive list of actors, and then choosing to have all sectors included. The second phase has started in early 2009 and concerns the choice and concrete implementation of one use case. The first phase is described in [10] and a few results are added for completeness. Personal interviews with 18 chosen partners were performed with the goal to have a qualitative evaluation of the needs of each partner concerning medical interoperability at the largest sense. The questions were taken as a basis for a longer qualitative discussion during the interviews. Interviews took around 120 minutes per partner and were moderated by several persons from the project (two persons per interview). The project partners developed questions together:

- Which electronic patient record is used and what exactly is digital?
- Which standards and terminologies are used, or even entire data models (such as HL7 RIM)?
- What is your attitude towards interoperability and data exchange? What is the potential and risks?
- Which scenarios would help you concretely in exchanging data (2-3 examples) with external actors?

Use cases chosen for a first reference implementation

Scenarios were defined in [10]. From discussions, 3 use cases were specified: (1) quick electronic release note, (2) electronic release letter, and (3) operation protocol. After discussion, it was clear that a prototype for exchanging release letters would provide the highest added value for GPs.

We defined the first specifications of the scenario with an architecture using a document server, as illustrated in Figure 2. The release letter (RL) is a short text summarizing the patient stay in a hospital. The medical doctor in the hospital (MD) directly writes it in free text (semi-structured) in the information system when the patient leaves the hospital. Currently, RLs are sometimes handed to the patient on paper, but most often sent by fax or mail, often several days after the patient leaves the hospital. The goal of RLs is informing the treating GP about the diagnosis, possible interventions, medications, as well as controls to perform.

The flow of events in the proposed use case can be summarized as follows:

1. The MD in the hospital creates a new release note;
2. The recipient of the document is chosen;
3. The document is generated partly with the data from the patient record;
4. The document is filled with diagnosis information;
5. The document is encrypted (encryption system has not yet been chosen);
6. The document is sent to the document server;
7. The server notifies the GP that a new document is available (GP requests the document on the next patient visit);
8. The GP connects to the server and creates a secure channel;
9. The GP downloads the document into its application using a secure channel;
10. The document is decrypted;
11. The GP checks the document and confirms its validity and correctness, then logs out.

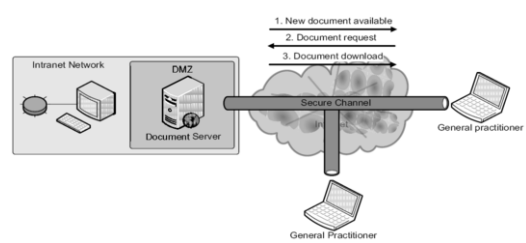

Figure 1 - The scenario of a document server inside each hospital and an exchange with external partners through a secure channel.

The MD is responsible for composing and sending the RL that will be archived in a MediCoordination repository hosted by the hospital (data is stored where it is produced).

[4] http://www.ihe.net/
[5] http://www.gs1.ch/

In this context, the MediCoordination prototype does not replace, but rather complements the traditional RL communication practices (mail, fax). Paper RLs are still sent to the GP alongside their electronic version for comparison.

Requirements for the reference implementation

Three main requirements for the prototype were sketched out from the results of the survey and from partners' expectations:

- it has to provide a measurable speed gain (orders of magnitude) compared to old practice (post mail, fax);
- it must not disturb the normal practice of the GP (transparent for the user);
- it has to provide interoperability with solutions already installed in medical offices (no IT changes or updates).

We collaborated with several GPs in the elaboration of a set of requirements for metadata and document formats. This process made clear that release letters are currently preferably produced in the Portable Document Format (PDF) format before printing them. For each produced document, we chose to generate metadata as XML documents including identifiers for the sending and receiving clinicians as well as for the patient.

Results

This section details the architecture of the prototype and the results we obtained with the current implementation.

Architecture

The prototype's architecture consists of a registry/repository and two clients, one for submitting documents (MD) and one for receiving them (GP). An XDS-based (Cross-Enterprise Document Sharing) server was used for both the repository and the registry. The IHE XDS Integration Profile describes an infrastructure based on standards (ebXML), for managing the information exchange of sensitive medical data between medical enterprises. A more recent version of the XDS profile (XDS.b), replacing the old one (renamed as XDS.a) was released. It supports SOAP 1.2.

The MHI prototype does not implement notifications. GPs have to manually query the registry. Once a document is downloaded it is archived and disappears from the server.

The MHI architecture in Figure 2 shows the interactions between actors. Corresponding IHE transactions are shown as link lables. The MD writes the discharge summaries for the patient and forwards it to the server along with predefined metadata. The client application of the GP then communicates with the server registry to query and retrieve the available documents. Client-server communications are channeled through a Web service endpoint in the bridge.

Server-side implementation

The server infrastructure (blue rectangle) is subdivided into two layers: an XDS.b implementation and a bridge. Bottom Layer : XDS.b

The backend server in charge of the XDS transactions consists of a Microsoft XDS.b Reference Implementation service. The registry and repository are both implemented as Windows Communication Foundation (WCF)/.NET services using standard Web communication protocols. Simple Object Access Protocol (SOAP) 1.2 is used for messaging, Message Transmission Optimization Mechanism (MTOM) for message attachments and WS-Addressing[6] for message delivery.

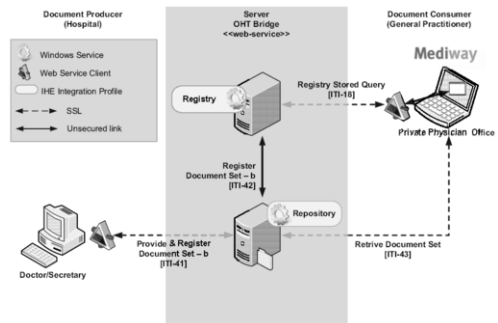

Figure 2 - Global view of the prototype with IHE IT Profile Transactions.

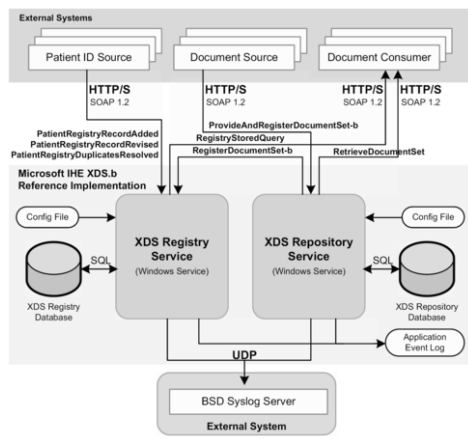

Figure 3 - Microsoft XDS.b reference implementation, including protocols and components.

The architecture illustrated in
Figure *3* shows Microsoft's XDS.b implementation. The prototype described here uses bidirectional (certificates in each side) SSL (Secure Socket Layer) encrypted communication channels between layers. The certificates are self-signed (for testing purposes).

Top Layer: OHT Bridge

iheprofiles is a subproject of Open Health Tools[7] (OHT), formerly known as Open Health Framework (OHF). It aims at facilitating the integration of IHE profiles into healthcare projects and consists of a plug-in oriented architecture. As shown in Figure 4, profile implementations are interfaced by

[6] http://www.w3.org/Submission/ws-addressing/
[7] https://iheprofiles.projects.openhealthtools.org/

plug-ins. A Web service end-point (OHT Bridge) then exposes functionality behind a unified interface.

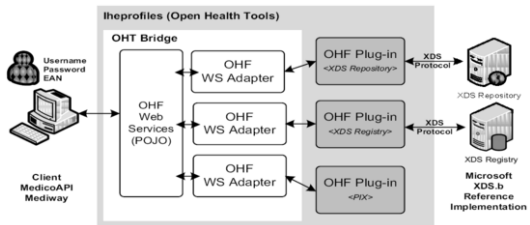

Figure 4 – iheprofiles integration in MHI

The bridge consists of many Web services encapsulated in an AXIS 2.0 container running on top of a Tomcat 6 server. Communications with the XDS.b server use SOAP 1.2 and SSL with self-signed certificates (SSC). Communication with the clients uses SOAP 1.1, SSL with SSC and token-based authentication (UsernameToken[8] from WS-Services).

The prototype uses a complementary access-control mechanism. Indeed, GPs and MDs have to provide an additional EAN-13 number in order to submit or retrieve documents. This additional credential is used to filter out documents that are not intended for the requested recipient. The EAN is kept in a database (currently a text file) along with the credentials.

Client-side implementation

The document source produces documents and the document consumer retrieves them. The prototype provides thus implementations for two types of clients.

Client-side implementation ─ Document Producer

A Java tool, CheckAppFolder, polls the state of the folder at regular intervals. When new documents are available they are forwarded to the bridge for registration and storage by the MedicoManager component, as illustrated in Figure 5.

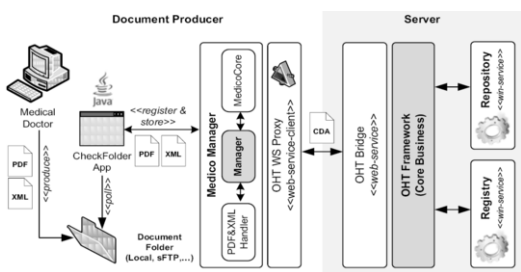

Figure 5 - Document Producer to Server integration

Documents found in the folder are base64-encoded and embedded in a HL7 CDA file by the MedicoManager component. This behavior follows from the fact that it is the only supported format by the bridge. Accompanying metadata files (in XML) are used to complete the associated CDA files before they are sent to the XDS server, and are mapped to XDS Registry.

Client-side implementation ─ Document Consumer

The consumer client is implemented in a modified version of existing well-disseminated software. Mediway[9] is an application for managing Electronic Health Records (EHR) of GPs. The modification was brought in the form of a .NET module, the OHT Connector, connecting seamlessly with the existing software. It is responsible for the communication with the repository and the registry (through the bridge).

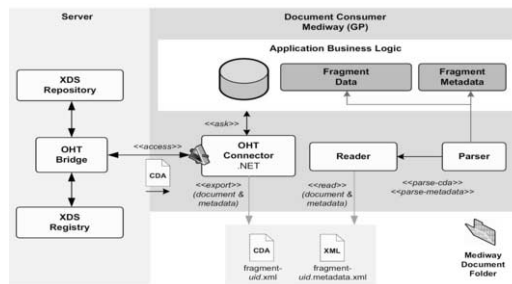

Figure 6 – Document Consumer to Server integration

The GP side prototype is shown in

Figure *6*. The system first reads the list of release notes targeting the GP from the registry. All documents are then downloaded from the repository and placed in a temporary folder chosen by the Mediway user.

The OHT Connector also produces accompanying metadata files. All documents are transferred in the original CDA format and require decoding prior to extracting information and then storing it in Mediway.

Timing and results

Two servers were used for testing the prototype. The first, H-Fr was installed in a state server farm for a hospital in Fribourg. The second, named RSV was installed on a physical machine in a hospital in Sion (Valais). Both servers have running instances of Microsoft XDS.b Reference Implementation[10] and ihetools[11], which are described previously in this paper. The first system runs a copy of Windows Server 2003 R2 on an Intel Xeon CPU @ 3.2 GHz with 1GB of memory. The second machine runs Windows XP Pro SP3 on top of a Pentium 4 CPU @ 3GHz with 1 GB of RAM.

All communication tests were performed on both servers using four different GP accounts and a reasonable amount of files for each situation. We measured timings and transfer rates with a T1 connection on a consumer PC. Obtained results are expected to prove the stability of the system for an arbitrary number of files, and confirm the clear advantage of an electronic system compared to the traditional paper release letters.

[8] http://docs.oasis-open.org/wss/2004/01/oasis-200401-wss-username-token-profile-1.0.pdf

[9] http://www.logival.ch/

[10] http://www.codeplex.com/ihe/

[11] https://iheprofiles.projects.openhealthtools.org/

For each server, we made a batch of measurements concerning the transfer time (TT) and the transfer rate (TR). The first measure indicates the elapsed time (in seconds) between the start and end of the download. The second measure measures the effective speed (kbps) of the download. For each measure we computed the max, min and average values. Data consisted of PDFs embedded in CDAs. Each file is about 4KB in length.

Table 1 - Timings and rates for H-Fr server

Statistic	UserA	UserB	UserC	UserD
Files	49	86	50	97
Total TT [ms]	6.45	10.66	6.37	11.79
Max TT [ms]	550.79	490.71	540.78	480.69
Min TT [ms]	100.14	100.14	100.14	100.14
Avg. TT [ms]	131.82	124.13	127.58	121.72
Max TR [kbps]	324.61	324.69	325.23	325.16
Min TR [kbps]	59.02	66.26	60.23	67.74
Avg. TR [kbps]	267.49	271.74	274.06	276.49

Table 2 - Timings and rates for the RSV server

Statistic	UserA	UserB	UserC	UserD
Files	23	23	18	26
Total TT [ms]	2.72	3.94	2.52	3.13
Max TT [ms]	200.29	480.69	480.69	180.26
Min TT [ms]	100.16	110.16	110.16	100.14
Avg. TT [ms]	118.81	171.55	140.20	120.56
Max TR [kbps]	295.10	295.10	295.67	324.77
Min TR [kbps]	162.31	67.64	67.74	180.60
Avg. TR [kbps]	278.05	231.47	278.94	274.49

File transfers were 100% successful (all files were transferred). Furthermore, results exhibited linearity (average values and total transfer time) as the number of files increases, which is representative of a stable system.

Discussion

In the context of interoperability, it is important that the information flow is quick and the GP is informed about the status of his/her patients as soon as they leave the hospital. A similar process can then be created for the admission of a patient, the full release letter, and other simple document types.

Traditionally, GPs used to query hospitals for the release letters and wait until they were sent or faxed. Upon reception, a RL had to be stored in the corresponding patient record. This process has inherent costs. The time elapsed between the query and the reception/storage counts in minutes. Our prototype reduced the process time to the millisecond range, which represents an important gain. Time lost for administrative tasks, is thus reduced.

Furthermore, with the integration of a module in Mediway, GPs accustomed to it did not have to change their habits and no additional expensive IT solutions were required.

Thus, results confirm our vision and prove that the solution is feasible. We managed to bring interoperability to actors that were until now isolated from the national eHealth strategy and relied on rather slow communication means. The experience is positive and our solution proved to have an added value.

Abstract

Introduction: Efficient use of health care resources in low-income countries by providers and local and national managers requires timely access to patient data. Objective: To implement electronic health records (EHRs) in HIV clinics in Kenya, Tanzania, and Uganda. Results: We initially developed and implemented an EHR in Kenya through a mature academic partnership. The EHR was then implemented in six HIV clinics in Tanzania and Uganda in collaboration with their National AIDS Control Programmes. All implementations were successful, but the system's use and sustainability varied depending on who controlled clinic funding. Conclusions: Successful EHR use and sustainability were enhanced by local control of funds, academic partnerships (mainly by leveraging research funds), and in-country technology support.

Computerized medical record systems, Developing countries, Africa South of the Sahara[*]

Introduction

Health care is an information business – most of what clinicians do is collect data (e.g. by history and physical exam), record data (in the patient chart), process data (choose treatments), and transmit information (via orders and letters). Information is necessary to provide and manage health care at all levels, from individual patients to health care systems to national Ministries of Health (MOH). The efficiency, effectiveness, accountability, and quality of health care at each of these levels depends on having accurate, timely data. In developed countries, electronic health records (EHRs) are becoming a necessary component of health care. For example, the U.K. and Sweden have national EHRs, and the U.S. has committed to wide use of EHRs by 2014 [1].

Developing countries trying to squeeze the most care from their limited health care resources have similar needs for timely health information. Yet being on the far side of the "digital divide" results in low-income countries having insufficient information to effectively manage their health systems. Since 2004, the U.S. Agency for International Development (USAID) committed more than $60 billion for HIV/AIDS care in developing countries. With more and growing HIV treatment programs, EHRs are becoming a necessity for managing and monitoring patients and health care systems while providing funders with data on the care provided and outcomes achieved. In this article, we describe our experience implementing OpenMRS [2], an open-source EHR, in three East African countries: Kenya, Tanzania, and Uganda. We evaluated each site and describe factors that led to successful implementation and sustainability of OpenMRS.

Implementing an Electronic Health Record System in Western Kenya

In 2001, Indiana and Moi Universities teamed with Moi

[*] The Tanzania-Uganda OpenMRS Consortium included National AIDS Control Programme of Tanzania (Dr. Geoffrey Somi), Morogoro Regional Hospital (Dr. Rita Lyamunya, Mayanga Mbaula), Ocean Road Cancer Institute (Dr. Hussein Mtiro, Willy Willifest), Tumbi Special Hospital (Japhal Mwamufupa, Joseph Myalla), Masaka Regional Referral Hospital (Drs. Penina Iutung, Kenya Mugisha, John Ssali, Michael Ssonko), Mbale Regional Referral Hospital (Dr. Peter Masaba, Helen Okwii), Mbarara Regional Referral Hospital (Dr. Mwebesa Bwana, Nneka Emenonyu), and the World Health Organization (WHO) (Dr. Mark Spohr, Christopher Bailey).
This work was funded by grants from the Rockefeller Foundation, WHO, the East African Consortium of the International Epidemiologic Databases to Evaluate AIDS, and the United States Agency for International Development as part of the President's Emergency Plan for AIDS Relief (PEPFAR).

Teaching and Referral Hospital (MTRH) to form AMPATH (the Academic Model Providing Access to Healthcare) and opened HIV clinics at both MTRH and nearby rural health centres. Anticipating their data needs, AMPATH and developers from the Regenstrief Institute developed an EHR to capture data from clinical encounters and provide AMPATH with data for both clinical care, monitoring and evaluation, and quality improvement. Initially, the AMPATH Medical Record System (AMRS) was a series of MS-Access® spreadsheets linked by patient identifiers and visit dates [3]. Following USAID funding in 2004, AMPATH grew to more than 15,000 patients who made 50,000 visits by mid-2005, overwhelming MS-Access®. Using the Regenstrief model [4], in 2006 we reconfigured the AMRS as a Java web application atop a series of MySQL databases. Through 2009, the AMRS supports HIV/AIDS, primary care, and specialty clinics 23 sites (rural health centres, district hospitals and Moi Teaching and Referral Hospital) contains 60 million observations from 2 million visits to 23 AMPATH rural and urban clinics by almost 150,000 enrolled patients, more than 110,000 of whom have HIV/AIDS. Figure 1 below shows the cumulative patients and visits in the AMRS from 2001 through 2009.

For each adult and pediatric visit, AMPATH's nurses and clinical officers complete paper encounter forms that were developed by AMPATH clinicians and managers to capture data for day-to-day patient care. Because clinicians' have the greatest need for detailed patient information, a system that captures sufficient data to serve clinicians' needs also serves the needs of local health system managers, national health programs, and international funding agencies [5]. Moreover, the same processes that capture clinical care can also capture data for non-clinical support programs. AMPATH provides care for HIV/AIDS and other conditions and collects clinical and non-clinical data as shown in Table 1. The AMRS currently employs 48 Kenyan data entry technicians, 10 data managers, 3 programmers, 3 information technicians, 2 biostatisticians, and 1 program manager.

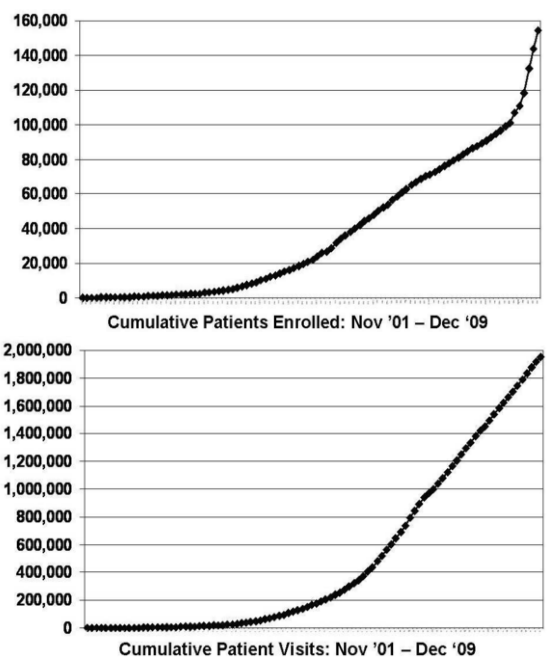

Figure 1- Cumulative patients enrolled and visit records

Table 1- AMPATH's electronic data collection

Clinics	Support Programs
HIV/AIDS – adults	Mother-baby register
HIV/AIDS – children	Social worker assessments
Primary care – adults	Outreach – patient follow-up
Primary care – children	Drug adherence assessments
Antenatal and postnatal	Nutrition assessments
Cardiovascular disease	Food supplement distribution
Pulmonary disease/tuberculosis	Microfinance program
Diabetes	Clinic pharmacies
Oncology	Clinical laboratories

Although all AMPATH care is delivered in Kenyan MOH facilities and mainly by MOH personnel, funding from USAID and other program-specific sources flows through Indiana University, Moi University, and MTRH. Investments by local AMPATH leaders in the AMRS to capture, manage, and analyze clinical data are recouped via enhanced provider and system productivity. Besides antiretroviral drugs (which are provided by USAID), care delivered by AMPATH cost only $175/patient/year in 2007 [6] and is now less than $100/patient/year in 2009.

In addition to the local monitoring and evaluation and routine and *ad hoc* reports required by funding agencies and the MOH, the AMRS also provides data to a robust multidisciplinary research program: researchers from Moi University and more than a dozen North American universities currently have more than 30 ongoing studies in East Africa, supported by >$40 million in grants from various U.S. federal granting agencies and foundations. Since 2006, Kenyan and North American AMPATH investigators have published >70 articles in peer-reviewed journals describing AMPATH care.

In early 2005, developers from Regenstrief and Partners in Health transformed the AMRS into OpenMRS [2,7] – a free, open-source EHR [8] and a community of developers who are creating a generalizable EHR to support health care delivery systems in developing countries [9]. To date, OpenMRS has been implemented in 25 countries, mostly low income, and supports HIV and a variety of other care programs.

The Rockefeller Foundation and the World Health Organization (WHO) observed that by having timely electronic data, AMPATH was able to deliver high-quality, evidence-based care. They then funded OpenMRS developers to test its usefulness to HIV/AIDS programs in other developing countries, specifically Tanzania and Uganda.

Implementing OpenMRS in Tanzania

In late 2005, leaders of the National AIDS Control Programme (NACP) of Tanzania expressed interest in participating in this OpenMRS demonstration. At the time, the NACP had implemented a paper-based HIV/AIDS registry that collected a core set of data on enrollment and at each visit, including vital signs, lab data, and treatments. The NACP had an electronic database for this registry, but few of these forms had been entered into the database or analyzed. Subsequently, there was scant information to support program management and strategic planning.

NACP leaders selected three sites OpenMRS for that varied in size, location, and experience with electronic data: Morogoro Regional Hospital (a large referral hospital, located 3 hours west of Dar es Salaam, that had prior experience with an electronic national hospital data system), Tumbi Special Hospital (a district hospital located on the outskirts of Dar es Salaam), and Ocean Road Cancer Institute (the site of care for AIDS-related malignancies) located near the NACP offices in Dar es Salaam). Neither of the latter two sites had any experience with electronic records of any kind.

In April of 2006, clinicians and data managers from each site and the Director of Epidemiology for the NACP met with OpenMRS developers in the AMPATH Centre in Eldoret, Kenya to learn about OpenMRS and develop adult and pediatric HIV/AIDS encounter forms. These forms included data required by the NACP plus additional information the clinicians thought would be useful for ongoing care. For guidance they used the AMRS encounter forms and a minimum dataset for HIV/AIDS care developed in 2004 at a WHO-sponsored meeting in Nairobi [5]. Also included in this 2006 meeting in Eldoret were computing and communication technology (IT) consultants from the University of Dar es Salaam who were contracted to program encounter forms and reports into OpenMRS and install and support it at each site. The United Nations Development Program provided computers and network hardware for all Tanzanian OpenMRS sites. The NACP supported data entry and management, aided by an epidemiologic research grant to Indiana University.

Because of high printing costs the desire for consistency with past data collection efforts, NACP leaders decided to forego the encounter forms developed by the Tanzanian clinicians and instead use their existing HIV registry forms. The computing consultants created a Patient Summary Report containing identifying data, diagnoses (HIV-related and others), drug allergies, HIV-relevant lab test results, and HIV/AIDS treatment data. This report was printed for clinicians before each patient visit to each demonstration clinic.

OpenMRS was first implemented at Morogoro in January of 2008 (Table 2). By the demonstration project's end in December of 2008, OpenMRS had been successfully deployed at all 3 sites, more than 11,000 patients had been enrolled, and OpenMRS had captured data from more than 58,000 visits. Patient Summary Reports were printed for most visits.

Reception of OpenMRS was generally positive. The university computing consultant independently maintained the system and generated reports for the NACP. Because OpenMRS was used to provide a database for the NACP's HIV/AIDS registry, implementing OpenMRS resulted in no fundamental changes in local clinic workflow and data management. However, by June of 2009 Morogoro had ceased to use OpenMRS.

Table 2- Implementation of OpenMRS in Tanzania with patients enrolled and visits stored through 31 December 2008

Tanzanian Site	Date EHR Initiated	Patients Enrolled	Visit Records
Morogoro	January 2008	5,204	23,436
Ocean Road	March 2008	621	3,707
Tumbi	July 2008	5,220	31,088
All Sites		**11,045**	**58,231**

Morogoro ceased its use of OpenMRS because its computer system failed and the consultant's contract ended. Subsequently, support was reestablished, and Morogoro is back using OpenMRS as a vehicle for capturing HIV registry data. Clinicians at Tumbi and Ocean Road Cancer Institute have continued to use their local versions of OpenMRS for all patients, sending electronic data to the NACP rather than paper HIV-register forms. Both Tumbi and the Ocean Road Cancer Institute continue to use the Patient Summaries.

Implementing OpenMRS in Uganda

The NACP and MOH in Uganda also participated in the demonstration project, choosing three sites differing in size, location, and university affiliation: Mbarara Regional Hospital (5 hours SW of Kampala, affiliated with the Mbarara University of Science and Technology), Masaka Regional Hospital (2.5 hours SW of Kampala), and Mbale Regional Hospital (4 hours NE of Kampala). HIV clinicians from these hospitals attended the April 2006 meeting in Kenya. Mbarara already had an MS-Access database (for data copied from patients' clinic notes) to support collaborative research with the University of California, San Francisco (UCSF). We contracted with a computing consultant at Makerere University in Kampala to install and maintain OpenMRS at all three Ugandan sites.

Each Ugandan site developed local encounter forms that captured data required by the Ugandan NACP and data that local clinicians needed to manage HIV-infected patients. The computing consultant installed OpenMRS at each site and programmed it to capture data from encounter forms and produce Patient Summary Reports and required reports to the NACP and MOH. Neither the Ugandan NACP nor the MOH required patient- or visit-level data from its HIV/AIDS clinics and as a result provided no support for OpenMRS. Research grants to UCSF and Indiana University paid for OpenMRS computer hardware, programming, and data entry.

Mbarara was first to initiate OpenMRS in January of 2007 (Table 3), employing seven Ugandan data entry technicians, a data manager, and one technologist, all with prior experience with their electronic chart abstracting database.

Table 3- Implementation of OpenMRS in Uganda with patients enrolled and visits stored through 31 December 2008.

Ugandan Site	Date EHR Initiated	Patients Enrolled	Visit Records
Mbarara	January 2007	9,854	12,869
Mbale	November 2007	1,601	,493
Masaka	January 2008	9,714	1,811
All Sites		**21,169**	**147,173**

Mbale had fewer HIV/AIDS patients and required one data entry clerk and one data manager. Masaka had three data entry technicians and one data manager. By the end of 2008, 21,169 Ugandan patients had been enrolled in OpenMRS at the Ugandan demonstration sites, with more than 145,000 visit records stored. Almost half of the patients and three-quarters of the visits were at Mbarara.

Care processes differed at the three Ugandan sites, and hence OpenMRS' effects on workflow varied. We assessed the effects of OpenMRS on workflow via a formal time-motion study [10]. At Mbarara, with experience with EHRs, patient visits after OpenMRS were slightly shorter (186 minutes pre-OpenMRS vs. 198 pre-OpenMRS, ($p<0.05$), with significantly less time spent waiting (88 minutes vs. 122 minutes) and more time spent with pharmacists (12 vs. 2 minutes) and non-clinical staff (61 vs. 42 minutes). There was no impact on provider time spent in various activities. At Masaka, which had no EHR experience, total visit time when up post-OpenMRS (102 vs. 77 minutes), all of which was due to increased waiting time (88 minutes increasing to 51 minutes). Yet there was a significant drop in time spent with pharmacy (1 vs. 3 minutes) and non-clinical staff (5 vs. 11 minutes). There was a statistically significant reduction in percent of the day clinicians (physicians, clinical officers, nurse practitioners) spent in patient care (43% of the workday pre-OpenMRS vs. 60%) and more time spent in administration (23% vs. 14%). At Mbale, a small clinic working out of two rooms, there were no significant changes in practice patterns.

Because only the Ugandan sites had fully implemented OpenMRS, we sent questionnaire Ugandan OpenMRS users (and not Tanzanian users) to assess their satisfaction with various aspects of the system. Respondents included clinicians, clinical support staff, and medical record clerks. As shown in Figure 2 below, users were highly satisfied with OpenMRS, finding it to be reliable and useful for performing their duties.

Currently, OpenMRS use continues at all three Ugandan sites. But Masaka has had problems paying for printing encounter forms, and data managers at all sites are being paid with research funds from Indiana University as part of an NIH-funded global HIV/AIDS epidemiology network [11]. Research grant funds from UCSF support OpenMRS data entry clerks and data managers at Mbarara.

Discussion

OpenMRS was initially, developed, implemented, and successfully supported rapidly expanding care in AMPATH clinics in western Kenya, aided by a long-standing partnership between Moi University, MTRH, Indiana University, and especially the Regenstrief Institute, one of the world's oldest and most active academic medical informatics institutions. Three decades of experience allowed Regenstrief investigators to replicate their data model into a new software platform (MySQL) that is able to support what is likely the largest clinical informatics enterprise in sub-Saharan Africa.

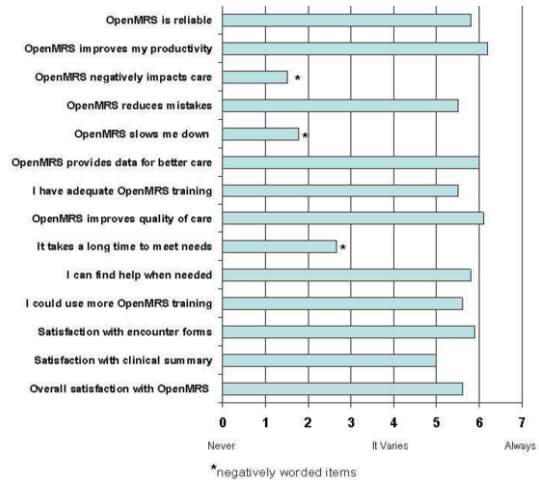

Figure 2- Results of OpenMRS user survey in Uganda

In Tanzania and Uganda, OpenMRS was successfully installed and used at all six sites. The most substantial and effective use was at Mbarara in Uganda, likely for several reasons: (1) Mbarara had previous experience managing electronic medical records via a small MS-Access research database. Thus they had both information technology in place and existing trained data entry clerks and data managers who could support the IT infrastructure, data entry, management, and reporting with minimum instruction. The local data manager was highly capable in programming as well as data management. Hence, problems with OpenMRS got solved quickly, usually by local staff able to work either alone or with help from Makerere University, Indiana University. (2) Mbarara University had a strong existing partnership with a sister university in the U.S. (UCSF). This led them to be friendly towards innovations and actually depend on data for both clinical care and research, even before OpenMRS was implemented. (3) Mbarara's clinicians and investigators had an incentive to perfect data collection to support future research. (4) And finally, a new clinic building was built just prior to implementing OpenMRS which was configured to accommodate OpenMRS' information technology infrastructure. Mbarara is a good example where a multi-disciplinary, multi-sector partnership was leveraged to enhance the implementation and rapid rise in use of an EHR. Such partnerships may be key to success in implementing health information technology in low-income countries.

Three factors influenced OpenMRS use in all three East African countries: local budgetary control, academic partnerships, and in-country IT support. AMPATH's local fiscal control and

global budgeting allowed it to pay for OpenMRS because it could recoup the cost through enhanced efficiency of care [12]. Pulling charts for scheduled patients facilitated patient flow while recording clinic data on a single form via tick boxes, numbers, and coded text (e.g., diagnoses). AMPATH could anticipate its personnel needs and avoid drug and lab stockouts. If control of local health care budgets resides in national MOHs, a local health care provider organization cannot pay for an EHR by increasing efficiency of care and lowering local personnel costs unless there is a national plan for installing and maintaining health information technology. Even then, EHRs will still need to be customized to serve local needs while serving the data needs of the government's national health care management and strategic planning.

EHRs that support local care can also provide sorely needed support for investigators and care programs in low-income countries. Research grants between North American and East African investigators helped implement and sustain OpenMRS in AMPATH [12] and all three Ugandan sites. Long-term sustainability and optimal use of EHRs to improve health care in developing countries, both locally and nationally, could therefore be enhanced by collaboration among academic, public, and private stakeholders [13,14]. Moreover, the resulting research could help identify strategies for more efficient and effective health care in low-income countries while supporting careers of local academic investigators.

Expertise in information and computing technologies, especially health informatics, is scarce in many low-income countries. Due to lack of medical informatics training in Kenya, the Regenstrief Institute trained all of AMPATH's local IT support staff and data managers. University IT consultants from the University of Dar es Salam supported OpenMRS in Tanzania while consultants from Makerere University in Kampala supported OpenMRS implementation in Uganda. These consultants participated in the OpenMRS collaboration and were thus backed by the global OpenMRS developer community which helped train them at annual OpenMRS Implementer Conferences and through online consultations. Such global developer communities can thus be a free and effective source of support for computing organizations that can then provide support to multiple EHR users in developing countries.

In conclusion, we successfully implemented a sophisticated EHR in HIV clinics in three East African countries. The locus of funding and oversight dictated the range of data captured, whom the EHR served, and how data were used to monitor, evaluate, and improve care. Local control of funds, academic partnerships, and enhanced local technical support bolstered developing countries' ability to implement and sustain EHRs to help low-income countries deliver, monitor, manage, and improve health care.

eHealth in Thailand: The current status

Boonchai Kijsanayotin[a], Narong Kasitipradith[a], Supasit Pannarunothai[b]

[a]Bureau of Health Policy and Strategy, Ministry of Public Health, Nonthaburi, Thailand
[b]Faculty of Medicine, Naresuan University, Phitsanulok, Thailand

Abstract

The World Health Organization (WHO) defines eHealth as the use of information and communication technologies (ICT) for health. Thailand is one of the leading countries in emerging and developing economy that the use of ICT applications is pervasive including eHealth. However, the status of eHealth in Thailand hasn't been assessed. Employing the WHO Global Observatory for eHealth development model and its instrument, this study describes the uptake of eHealth foundations and the extent of eHealth applications and services implemented in the country. A group of the nation 18 eHealth experts met and evaluated country eHealth status and provided recommendations. The results show that the development of the country's eHealth foundations is inadequate and need to be the priority for national eHealth development.

Keywords: eHealth, Thailand, Evaluation study

Introduction

The World Health Organization (WHO) identifies fully functional health information system as one of the six important building blocks of high performance health system[1]. To understand a country's health information system, it is essential to understand the extent of information and telecommunication technology (ICT) use in her health system, because, in the world today, information systems and ICT are closely related and amalgamated to be an almost inseparable entity. WHO broadly defines eHealth as the use of ICT for health. eHealth has the potential to address inequities in health systems and services in countries. Its applications span across a wide range of areas such as the use of ICT to: 1) store, process and transmit patient information 2) manage the diverse clinical, administrative and financial information generated in health services facilities 3) improve quality of patient care and patient safety 4) provide mechanisms for diagnostics and treatment between health professionals separated by distance 4) build capacity by offering health sciences training and continuing education courses online to students and health professionals 5) offer innovative approaches for health care using rapid growing mobile devices 6) make highly complex biomedical research achievable[2]. Thailand is one of the countries that have achieved an elevated level of access to and use of ICTs and ICT skills (rank at the upper group countries by ICT Development Index -IDI)[3]. However, the status of eHealth hasn't been evaluated in Thailand. This study was conducted in the collaboration between Thailand's Ministry of Public Health and the WHO Thailand to analyze Thailand's eHealth current situation and identify the country's eHealth development gaps. The project aims not only to help Thailand assess her current status on practices, policies, standards, and the implementation of eHealth but also to contribute to the Global Observatory for eHealth second survey[4]. Moreover, the gaps identified from the survey will help health policy-makers at the ministerial level to plan for improving the nation's eHealth.

Methods

This study employed the WHO Global Observatory for eHealth's (GOe) development model and its second survey instrument. The GOe's questionnaire was designed to identify and analyze trends in 1) the uptake of eHealth foundations and 2) the extent of eHealth applications and services implemented. The questionnaire consisted of close end questions and open end questions asking participants to describe eHealth activities and projects in the country, including comments which participants considered relevant to the survey. We identified and invited 18 experts from both public and private sectors to participate in the survey. They are experts in health systems, health information systems, and ICT from Ministry of Public Health, public and private hospitals, National Health Security Office (the office of country's universal insurance scheme), National Statistics Office, Ministry of Information and Communication Technology (MICT), International Telecommunication Union (ITU), National Electronics and Computer Technology Center (NECTEC), medical schools, universities, health informatics professional association and health information non-government organizations (NGOs). These experts are working on various aspects of eHealth activities in the country. All experts accepted the invitation. The questionnaires were sent to the experts three weeks before a full-day discussion and consensus meeting. We asked them to study the questionnaire and be prepared for the discussion to get the country's consensus on eHealth. The

consensus and experts' recommendations are compiled to represent current Thailand eHealth.

Results

eHealth foundations

Since 2000, Thailand has a national ICT policy/strategy framework (IT 2010 framework) and two five years national ICT master plans[5][6]. The framework and plan has been implemented since 2002.The national ICT framework laid out e-strategy for eGovernment, eEducation, eCommerce, eSociety, eIndustry but not eHealth. As the results, the country has no national eHealth governing body that provides leadership and direction. Although there is no national eHealth policy/strategy, many eHealth applications and services has been developed, piloted and implemented. Major funding of the projects comes from public sector, the government. A few eHealth projects have been supported by public-private partnerships and health information NGOs. Even though, there are few public-private partnerships, the partnership between the Thai Medical Informatics Association (TMI), MOPH, public universities and NECTEC to organize annual health information and health information technology conference has been carried on almost two decades.[Table 1]

For eHealth capacity building, the human resources skills and knowledge, ICT skill and knowledge training courses have been offered for students of health sciences in more than 75% of tertiary educational institutes in Thailand (public and private). There are also institutions/organizations, such as MOPH and universities offer continuing education in ICT for health as part of the ongoing training of health and allied health professionals. Nevertheless, the short term training courses and degree training courses in biomedical/health informatics has not been instituted.

Although Thailand has enacted a legislation to ensure privacy of personally identifiable data of individuals irrespective of whether it is in analog or digital format, the country doesn't have a specific legislation to protect privacy of individuals' health-related data held in digitized format. The country doesn't have legislation which provides for the sharing of health-related data between health care staffs through an Electronic Medical Records/ Electronic Health Records (EMR/EHR) at all level of health care services. It means that there is no legislation about the data sharing 1) within the same health care entity and its associated network of care providers, 2) with different health care entities 3) with health care entities in other countries. Moreover, the country has no 1) legislation which grants the right of access by individuals of their health-related data when held in an EMR/EHR 2) legislation which allows individuals to demand the deletion of personal data and/or health-related data from their EMR/EHR 3) legislation which allows for the transmission and sharing of research data containing personal and health-related data between research entities in different countries and 4) legislation about the legal right to specify which health-related data from their EMR/EHR can be shared with health provider(s) of their choice. Regarding online pharmacies in Thailand, there is no legislation that either allows or prohibits internet pharmacy operations and no mechanism that regulates, accredits or certifies internet pharmacy sites. Furthermore, the legislation that allows or prohibits internet pharmacy sales purchased online from other countries hasn't been enacted in the country. In short, Thailand doesn't have laws to keep up with the rapid changing online pharmacy business. In terms of children protection from online risk, Thai government has sponsored websites or official initiatives to provide appropriate information and education about internet safety and literacy. These efforts aimed to protect general population and children, in particular. However, there is no safety tools and security technologies required by law for schools, libraries and other public places with internet facilities used by children.

Table 1-Summary of eHealth uptake in Thailand

eHealth Development	Uptake
I. Foundation Policies & Strategies	
1. National eGovernment policy & strategy	√ ICT2010
2. National eHealth policy & strategy	X
3. National eHealth governance body	X
3. Funding	+ Public, No Private
4. Public & Private partnership	+
5.Infrastructure	++
II. Enabling Policies & Strategies	
1. Health information security & privacy laws	X
2. Actions on Multilingualism & Multiculturalism	X
3. Capacity building	++
3.1. IT courses for health science students	+++
3.2. IT courses for health professional	+
4. National health IT standards (Interoperability)	+
4.1.Core data set standards	12 & 18 files standards
4.2.Semantic standards	ICD 10 TM, ICD 9 CM
4.3.Syntactic standards	X
4.4.Security and privacy standards	X
III. eHealth Applications	
1. mHealth	++, mostly pilot
2. Telemedicine	+, pilot
3. eLearning in health sciences	+
4. EHR/EMR (Health Information Exchange)	++
4.1 For administration, claims	+++
4.2 For clinical care	+

Note: √ = Adopted, X = No uptake, + =0-25% uptake, ++ = 26-50% uptake, +++ = 51-75% uptake, ++++ = 76-100% uptake, ICT 2010 = Thailand ICT development frame work 2000-2010, ICD 10 TM = International Classification of Disease version 10 Thai Modification, ICD 9 CM = ICD9 Clinical Modification procedure codes.

Regarding Multilingualism and multiculturalism in eHealth, the country has no national policy or strategy that promotes the production of electronic health information in a manner that is multiculturally sensitive. Although at the three southern most provinces of Thailand there is a large number of Thai Muslims. Their dialect, religion and culture are differences from the traditions and language of the majority Thais. The experts agree that this issue should not be ignored and identified this issue as one of the national eHealth priorities.

At the national level, ICD10-TM (International Classification of Diseases version 10-Thai Modification) and ICD9-CM (Clinical Modification) are used for coding diagnosis and health service intervention respectively. Thailand has developed and implemented citizen identification number for more than two decades by the Ministry of Interior. Every Thai citizen has a unique identification number, known as "13 digits number". It is also used as patient identifier. There are two national health minimal data set standards which are developed for administrative purpose. They are 1) standard data sets for health insurance, known as the "12-file data set", and 2) standards data set for health center, known as the "18-file data set".[7] They are used mainly for health insurance payment and healthcare activities reports. National drug code, national health provider identifier, medical device coding standards, survey metadata standards, indicators standards are at various stages of development. HL7 messaging and LOINC standards (Logical Observational Identifiers Names and Codes - a laboratory coding standards) are implemented in a few large hospitals. They are not the national standards. DICOM (Digital Imaging and Communication in Medicine), a standard for handling, storing, printing, and transmitting information in medical imaging, is used in many health facilities in the country usually where PACS (Picture Archiving and Communication Systems) are implemented. However, it is not instituted as a national standard.

eHealth applications and services

The mix of paper and computerized patient information (individual data and aggregated data) are being used in healthcare services. In public sector, almost all of hospitals (1,001 hospitals) and health centers/primary care units (10,068 PCUs) have implemented various degrees of capabilities of EMR/EHR. If we categorize individual patient information into administrative data (used for reimbursement, administration and reports) and clinical data (for patient care e.g. laboratory data, pharmacy data, providers' notes), these two data type are not equally developed in Thailand. Administrative data are computerized and can be transmitted and exchanged electronically in nearly all health facilities in Thailand. The clinical data are collected in both paper and computerized format but the capability to exchange electronically is very limited.[Table 1]

Thailand doesn't have a national telemedicine policy or strategy and also a national agency for the development and promotion of telemedicine and its applications. Furthermore, there is no scientific institution involved in the development of telemedicine solutions in the country. In the past decade there were many telemedicine projects and activities. Many of them were short term demonstration projects which were the works between international agencies and Thai's universities or big private hospitals [8-10]. There was only one national telemedicine project implemented by the MOPH during 1998-2003, called MOPH's telemedicine network.[11] This big project aimed to deliver medical care to people in remote rural areas where there were the shortage of doctors and other professionals. However, the project was not very successful and was abandoned in 2003. There were many factors contributing to the ending of the project, for instance, no national body to continuously provide national telemedicine policy and strategy, the lack of requisite IT skills among health professionals, the country's economic crisis, the rapid changes in technology, and the rapid social and political changes taking place in Thailand. Currently, there are private teleradiology services which provide services largely for big private hospitals in big cities. Several public telemedicine pilot projects are being piloted such as the teledermatology consultations which run by Institute of Dermatology, MOPH.

mHealth is an emerging term for medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, Personal Digital Assistants (PDAs), and other wireless devices. mHealth applications include the use of mobile devices in collecting community and clinical health data, delivery of healthcare information to practitioners, researchers, and patients, real-time monitoring of patient vital signs, and direct provision of care. In Thailand, several mHealth initiatives are being piloted and implemented. The cross-border Mekong Basin Disease Surveillance System is an example of a piloted mHealth project which uses mobile devices for diseases surveillance and management of emergency and disaster situations. The project uses GeoChat SMS groups communication software developed by InSTEDD to report communicable diseases and emergency occurred in community in Mukdahan province (Thailand) and Suvanakhet (Laos). The public health personnel working in the sub-district level use SMS format to report cases in order to improve timeliness of report and warning for potential disease outbreak and disaster.[12]

In Thailand, eLearning program has been used to teach health sciences students and the development of continuous health professional training programs in many institutes. At the national level, the use of eLearning to teach health sciences students was estimated at medium level (more than 25% and less than 50% of institutes and/or courses). But the level of use for professional development programs in the ongoing training of health professionals was estimated at low level (less than 25%). Thailand Cyber University Project [13], operates by the Commission of Higher Education, Ministry of Education, provides supports to the eLearning programs development for students and non-students to teaching institutes in the country

including health sciences teaching institutes. A number of health sciences eLearning courses are available at its website.

Discussion and conclusions

Among developing countries, evidences show that Thailand is one of the leading countries that the use of ICT applications is pervasive including eHealth [3, 14]. However, our study reveals that the country is lag behind in laying down the eHealth foundations. The WHO GOe identifies three layers of eHealth development.[2] [Figure 1] The first layer, the foundation policies and strategy, forms the basis of country eHealth development. This includes the creation of an appropriate governing body—a multi-stakeholder, national-level, eHealth authority to provide leadership and direction, the development or adoption of eHealth policy to define the vision and action required, the development of a funding framework to support the vision, and mechanisms to develop ICT infrastructure for the provision of eHealth services. Although Thailand has national e-strategy for various sectors, but the vision and strategy for eHealth haven't been laid out. This may be both the cause and result of not having national eHealth governing body.

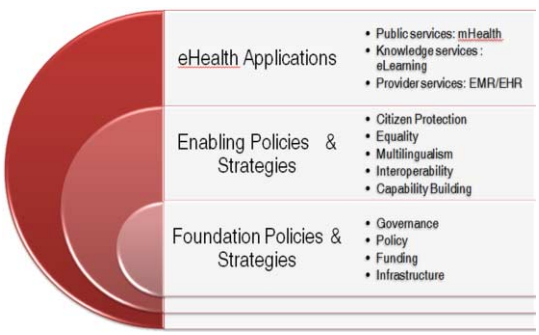

Figure 1-The Global Observatory for eHealth Development model (modified)

The second layer of eHealth development model, consists of enabling actions, which broadly act as a bridge between foundation policies and strategies and the planned outcome of providing eHealth services for all. The functions of enabling actions are to protect the citizen, promote access and equity, and to act on the need for multilingualism and multiculturalism in cyberspace. They include eHealth interoperability policies and strategies to ensure that systems can communicate with each other. Finally, they include a component to build the ICT capacity of health professionals and students. Consider components in this layer, Thailand doesn't take action on multilingualism and inadequately takes actions on citizen protection, eHealth capacity building and interoperability of systems.

The third layer, eHealth applications such as EMR/EHR, mHealth, telemedicine, are being implemented in Thailand, but these services are fragmented and scattered. It is known that, the success of these applications is largely dependent on the actions leading up to them, that is, services in this layer will be more effective if the actions in the first two layers have been executed well. Solid foundational layers lead to more effective eHealth systems and services. Unfortunately, Thailand is inadequately taking actions on developing these two layers.

The country's eHealth experts recommended that the country should put the development of eHealth foundations the priority. The identified foundational gaps should be closed to enable the development of sustainable and effective eHealth systems and services. The recommendations are 1) Thailand should create a multi-stakeholder, national-level, eHealth governing authority to provide leadership and direction, the development or adoption of eHealth policy to define the vision and action required 2) the country new national ICT framework, ICT 2020, should incorporate eHealth strategy into the framework along with eGovernment, eEducation, eIndustry,eSociety and eCommerce 3) legislations related to health information security, privacy and confidentiality should be enacted to protect people 4) national health information standards need to be developed to enable eHealth services interoperability and health information exchange and 5) systematic mechanism for capacity building of people who design, implement, operate and use of the eHealth systems has to be planned and implemented

Acknowledgements

The authors gratefully acknowledge all experts who participated in this study. We thank Mrs Maliwan Yuenyongsuwan and her staffs at the Bureau of Health Policy and Strategy, Ministry of Public Health for their secretariat support. We express our gratitude to Dr. Sombat Thanprasertsuk,WHO Thailand Country Officer, and his staffs for their support. The funding source of this project was from WHO Thailand, project activities proposal number 080315.

Abstract

This paper sums up some of the findings from a national survey on the diffusion and use of Electronic Health Record (EHR) systems in the Norwegian health sector. The survey shows that almost all hospitals and GPs use their EHR systems on a daily basis, while the municipalities are lagging behind, All three view costs and missing functionality as the most important challenges. The GPs are very concerned with the complexity of the daily operation of the systems, while the hospitals are mostly concerned with costs of daily operations, maintenance and further development of the systems. Better integration with support systems is requested. User involvement and ownership seem to have contributed to the development and diffusion of the most successful EHR systems. National diffusion processes require good planning and are time consuming. It has taken 15 years from the first EHR systems were introduced until 90% of the actors used the systems. This has to be taken into account in national strategy processes in the health sector.

Keywords:
Electronic health record, Shared care, Survey, Benefits, Diffusion, Strategy

Introduction

The Norwegian Directorate of Health did a strategic study on EHR strategies in the Norwegian Health Sector 2005. The study pinpointed the need of "a better decision base for further development of EHR systems". More documentation on the diffusion of existing EHR systems and also their usage and potential benefits in comparison to paper based systems was requested.

An increasing focus on shared care that involves health workers from different organizations, leads to more transfer of a patient's health information across organizational boarders. This extensive information exchange will also imply new requirements and challenges regarding further development of the EHR systems that are used by the collaborating actors.

So far, data about clinicians' use of EHR systems in Norway have only been gathered and analyzed in relation to hospitals by Lærum et al [1], Ellingsen and Monteiro [2] or at a local level by Christensen [3]. Examples of documentation regarding EHR diffusion in other countries are Castro's report on leadership in Health IT [4], Protti and Nilsson's comparison of IT in general practice in ten countries [5] and Nøhr's analysis of development, implementation and diffusion of EHR systems in Denmark [6, 7] and Gans et. al [8]. In order to get a better overview of the Norwegian status, the Directorate of Health initiated the EHR Monitor project. The project will monitor the implementation and use of EHR systems each year. Data will be retrieved by surveys. This paper sums up some of the findings from the first survey, and also sees some of the findings in relation to existing research related to diffusion of EHR systems.

Method

The questionnaire

The purpose of the first survey in 2008 was to collect quantitative data as a basis for further study based on a set of indicators. Examples of indicators are the number of hospitals, GPs or nursing homes that use EHR systems and the number of actors that plan to implement such systems within a fixed number of years. The researchers have found it necessary to use both open questions where the user can answer quite freely, and questions that require quantitative input.

Four different types of questionnaires were developed, one per type of actor in the survey: GPs, municipal health stations, nursing homes and hospitals. The questionnaires were developed through workshops, expert feedback and pilot testing.

It was assumed that the informants had little time available for paperwork, and it was thus decided to use questionnaires that could be filled out with limited use of time. The questionnaires were also intended for reuse in order to provide comparable data over a period of two or more years. It was decided that the number of questions should be held within the limit of 4 pages. It was assumed that several reminders would be required to get the forms returned or until a negative answer to the request would be given. The GPs received compensation

comparable to a patient consultation as a compensation for loss of income.

Selection of informants: The survey was directed towards GPs, municipal care and hospitals. 180 municipalities were selected based on size and geography in such a way that they could be regarded as representative for the national average. 150 GP practices were included. 130 of these were selected based on a random pick among the selected municipalities. In addition 5 practices from each of the four largest cities were included. The questionnaire was sent to all the hospitals.

The response rate was: 43% from the municipalities, 62% from the GPs and 83% from the hospitals. The number of forms returned from the GPs and hospital were quite high, but a better response from the municipalities had been appreciated. The fairly low response from the municipalities might be due to the fact that a more general survey on ICT use had been sent to the municipalities not long before the her Monitor survey.

Results

The most visible indicators for dissemination of EHR systems in the health sector are the share of actors that use these systems. This is illustrated in figure 1. The survey shows an almost full coverage among GPs and hospitals. It has been 20 years since the first EHR installation in a hospital until full dissemination. The same process started earlier among the GPs, and their adoption curve was even steeper. The use of EHR systems in municipal care (nursing homes and maternal and child health centers) is more limited, but seems to follow the same trend. The smaller municipalities are slower to introduce new ICT-solution than the larger ones.

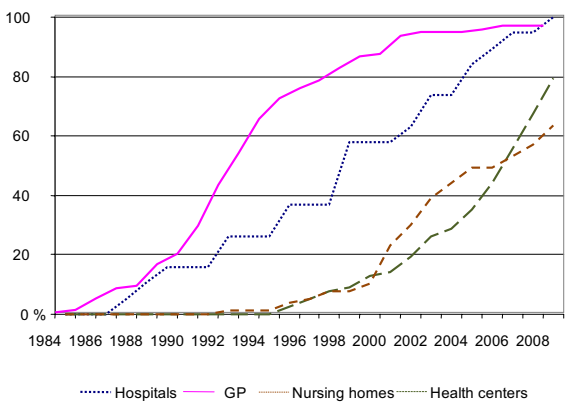

Figure 1- Planned or fulfilled implementations of EHR systems

The GPs do not keep paper records any more, but only 25% of the hospitals have a completely paper free record. Some of these hospitals scan selected parts of the record that have been preexisting in paper form when the patient is admitted. 65% of the hospitals use the electronic record as the main source for medical information. There are also regional differences in the use of paper free EHR. 75% of the hospitals in Mid-Norway do only use the EHR, while 70% of the hospitals in South-Eastern Norway still use the paper record as the main archieve.

83% of the municipalities reported to use some kind of EHR system. EHR systems are used in nursing homes (82%), home-care services (56%), school health services (39%), community habilitation services (34%) and maternal and child health centers (65%). The smaller municipalities with less than 2500 inhabitants are the slowest ones when it comes to adopting new systems. This can be related to relatively high cost for both buying new systems and daily operating cost for the systems.

6% of the municipalities were using PDAs with access to the patients' EHR in the home care services. Another 12% reported that they were about to implement PDA systems the following year.

The informants in the survey were also asked what they saw as the main challenges in relation to future EHR use.

Table 1- The hospitals reported challenges regarding further diffusion and development of EHR systems

	All answers	Most important	Sec. most important
High costs	80 %	44 %	15 %
Missing functionality	50 %	13 %	15 %
Complexity in daily operation and maintenance	28 %	3 %	3 %
Resistance against change among users	10 %	5 %	-
Missing standards	35 %	8 %	9 %
User education	40 %	5 %	3 %
Missing integration	63 %	5 %	30 %
Realization of benefits	53 %	8 %	9 %
New government requirements	20 %	3 %	0 %
Vendors that do not deliver as promised	55 %	5 %	12 %

Both groups saw rising costs and missing functionality as the most important challenges. The GPs were particularly concerned with the complexity of the daily operation of the systems. Integration between the main EHR system and other clinical and administrative systems at the hospital is also a great concern. Improved functionality is highly requested by all actors. Further, it has proven to be difficult for the hospitals to realize the expected gains and benefits from the new systems, and vendors do often not deliver their new version on time.

The hospitals were less satisfied with their vendors than the municipalities and the GPs.

Table 2 - The GPs reported challenges regarding further diffusion and development of EHR systems

	All answers	Most important	Sec. most important
High costs	54 %	34 %	7 %
Missing functionality	36 %	9 %	13 %
Complexity in daily operation and maintenance	52 %	13 %	22 %
Resistance against change among users	8 %	-	3 %
Missing standards	29 %	4 %	10 %
User education	18 %	3 %	4 %
Missing integration	44 %	11 %	16 %
Realization of benefits	28 %	3 %	4 %
New government requirements	15 %	3 %	4 %
Vendors that do not deliver as promised	27 %	10 %	4 %

The hospitals were also asked about their possibilities for electronic message exchange. It is important to emphasize that it is a gap between possibilities for use and actual use of electronic message exchange. This is both due to the fact that not all collaborating actors have EHR systems that can communicate, and that not all organizations are ready to use the collaboration possibilities. 59% of the hospitals have systems that can receive electronic referrals, 100% can send electronic discharge summaries, and 91% can send laboratory reports.

24% of the General Practices send electronic referrals, but more than 50% of these referrals are sent with paper referrals in parallel. More that 90% of the discharge summaries and laboratory reports are received electronically by the GPs, but paper is also sent in parallel with 55% of the discharge summaries and 45% of the laboratory reports.

Discussion

The diffusion curves of the Norwegian EHR systems all seem to follow the same s-shape. The starting point differs (Figure 1), but the norm is that it takes at least 15 years from the first systems are introduced until 90% of the actors use the system. In an evaluation of ten European projects [9] it was shown that the factors that influenced the diffusion time most, were dependencies to existing software and infrastructures. A break/even point for costs and benefits would in most projects be reached after five years. This is a challenge when it comes to realization of ICT strategies because the planning horizon is too short. Our finding are in line with Bower's suggested adoption rate for EHR [10], where he compares diffusion of EHR with diffusion of ICT systems in other industries.

Diffusion of EHR systems among General Practitioners

The first EHR systems for Norwegian GPs were in use as early as in the late 1970ties. This was the PROMED-system [11]. Another system was installed in Balsfjord in 1980 [12]. The development of the Balsfjord system was financed by research grants and government funding. The system did only have a limited number of users in Northern Norway. The GPs outside the Balsfjord-project did not get any subsidies or incentives from the government when the new EHR systems were introduced. They had to buy the systems themselves, but found the new systems so useful that they were worth the investment. Later EHR systems in general practice have all been developed without any subsidies or incentives.

The first systems were based on use of the operating system MS-DOS. The market leader during the first decade was Infodoc [13]. When new systems that used MS-Windows were introduced, many of the users did not only change version of their system, but also vendor. This process is illustrated in the figure below. This shift took place in the period 1999-2001.

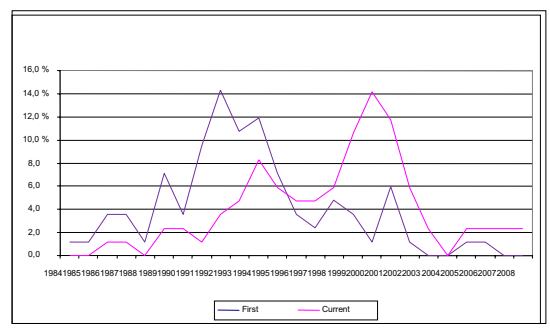

Figure 2 – GPs' purchase of EHR systems

An international survey in 2007 [14] showed that 98% of the GPs in Finland, Denmark, Norway, United Kingdom, the Netherlands and Estonia use ICT-systems to support their daily work processes. An American survey [15] from medical group practices in the USA showed that adoption of EHR systems progressed slowly, at least in smaller practices, although a number of group practices planned to implement an EHR within the next two years. The process of choosing and implementing an EHR system appeared to be more complex than first expected.

Tom Christensen [3] has in his doctoral thesis analyzed how GPs use EHR systems and how they can be developed further in order to better support the GP's work processes. The GPs reported that they generally believe that using the computer saves time, and observations showed that they used even less time than reported in front of the computer. On the other hand they also tell that the introduction of EHR has transferred

workload from the secretary to the GP. They are generally satisfied with their system, but need better decision support and support for communication with other systems even if possibilities for message exchange have been made available in most of the systems. They also reported that it had become more difficult to get the overview of the patients' earlier health-history. The clinician-patient relationship is of great concern GPs, but they denied that the use of an EHR system drew the attention away from the patient.

Diffusion of EHR systems in Norwegian hospitals

The diffusion of EHR systems in hospitals has been much slower than in primary care. Ellingsen and Monteiro [2] stated that establishing EPRs in hospitals, especially the larger ones, has been notoriously difficult. The increase in organizational, institutional, political and technological complexity was seriously underestimated during the first years. Before the introduction of EHR systems in hospitals, patient administrative systems had been available in hospitals for a decade.

The benefits have not been equally visible when it comes to health record systems that can support the clinicians' daily work-processes [3], [15]. The clinicians in hospital often move over long distances during their workday and uses EHR systems only a few minutes at a time. It has been shown that information resources must be easily available in the clinicians' workspace in order to be used [16] In the EHR Monitor survey 80-90% of the hospitals agree that there are big potential quantitative and qualitative benefits related to the introduction of EHR systems, but only 20-30% agree that these benefits already have been achieved. It is common that it takes some time from the ICT-systems first are introduced until the benefits can be achieved. It is however surprising that the survey showed that less than 50% of the hospitals had a plan for realization of benefits related to the introduction of new systems.

In comparison to the development of EHR systems for the GPs, the government has provided significantly more funding for the development of hospital's EHR systems. Still the diffusion time has been much longer. This is probably due to the complexity of hospital organizations, and the large amount of work required for integration with many different information systems at the hospitals. Another difference is that the GPs have been planning, ordering and using the new systems themselves. They have not bothered to invest in systems that could not provide them with obvious benefits neither in terms of reduced cost nor as support for their daily work processes. On the hospital side, most of the procurement processes have been managed by the administration. The health workers have often been involved in the requirement specification processes, but their possibilities to grasp how these specifications would influence on their work processes have often been limited, simply because many of these systems are very complex.

Three major EHR systems are in use in Norwegian hospitals today, of which one is on the way out of the market. One vendor has a significantly larger market share than the others. This system originated from a small Norwegian hospital and the first version was developed in close collaboration with the users at the hospital. This contributed to the making of a system that to a high degree supported the health worker's daily work processes. From being a system that should support a limited number of users, the system is now in use at many, both large and small, hospitals. This can be a challenge when it comes to user involvement in the design process and flexibility to satisfy diverse requirements. The study showed that 67% of the users of this system were dissatisfied with the functionally of systems with the largest market share versus 33% of the users of one of the other systems that have been used by the same hospitals for a long period of time.

The company has now started to use agile software development. Agile software development refers to a group of software development methodologies based on interactive development, where requirements and solutions evolve through collaboration between self-organizing cross-functional teams. Agile methods are also used by at least one of the vendors of EHR systems in primary care.

EHR systems in municipal care

The first EHR systems were introduced to municipal care as late as in 1995. The municipalities have the responsibility for a diverse set of ICT-services in order to serve schools, technical offices, administration and health care. Benefits related to introduction of ICT-services in other sectors than health care may have been more obvious, and may have led to a reduced focus on the EHR systems.

The diffusion curve for EHR systems in nursing homes and at health stations now seems to follow the same pattern as for the hospitals and GPs.

The municipalities seem to be very optimistic regarding future benefits of mobile solutions, but research [17] also indicates that at least in the introduction phase, the nurses will spend significantly more time using electronic mobile solutions than paper.

Conclusion

Costs, both related to purchase and maintenance are important for all actors. Expectations of possible future qualitative and quantitative benefits of the systems seem to be high, but cost/benefit analyses are to a large extent lacking.

User involvement and ownership are important for the success or failure of EHR systems. The GPs have been closely involved in the design of EHR systems from the beginning. The most successful EHR system for hospitals did also originate from a hospital setting. This is likely to have contributed to the making of a system that worked well in a real life hospital setting.

The installed base of EHR systems is growing, and this is also a challenge when functionality is lacking and new extensions and functions need to be added to the existing system. EHR systems are not static, and even if many of the modules will remain stable over time, new and innovative modules needs to be developed. New health reforms and technology changes will also put pressure on vendors for further development of the systems. More extended user involvement, use of agile

system development methods and reusable components may make this process easier in the future. The large existing installed base of software, however, can also be a challenge potentially limiting for rapid development.

A diffusion process of systems that shall be used on a national basis requires good planning and is time consuming. This has to be taken into account in national strategy processes for the health sector.

The EHR Monitor survey gives an indication of how many actors in municipal care that use today's EHR systems, but not necessarily of how they use them. Further work is needed in order to get a better understanding of how the systems are used as support for daily work processes.

Abstract

Numerous eHealth projects and efforts to establish inter-organizational communication and to build up regional health care networks could be observed in the last ten years. Nevertheless the success of such efforts is profoundly different. The aim of this paper is to introduce the lately started regional initiative eHealth.Braunschweig compounding of the major health care players (hospitals, physician offices, nursing services and nursing homes) in the region of Braunschweig, participants from research institutions and industry. We propose in this paper the main goals of the regional initiative eHealth.Braunschweig, its constitution and major approaches. Based on respective literature and our former projects as well as experiences in this field we discuss our vision of a patient-oriented cooperative health care by depicting regional distinctions, identifying the major domain fields in this context and discussing the architectural challenges for the regional health care network eHealth.Braunschweig. In our view this work can be considered as a systematical approach to the establishment of regional health care networks with lasting and sustainable effects on patient-centered health care in a region.

Keywords:

Regional health care networks, Collaborative care, Integrated health care systems, Interdisciplinary communication

Introduction

Medical collaboration and cooperation is considered as an essential need to achieve high-quality and patient oriented health care beyond sectoral boundaries of primary care, secondary care, outpatient care, rehabilitation or home care [1]. Also the application of information and communication technologies in health care systems and the establishment of regional health networks have a positive effect on the data exchange and access, effectiveness of patient care, and communication and coordination within a region [2], [3], [4] and [5].

Although computer based information and communication technologies have been used in health care facilities for several years and electronic medical records within health care institutions are already common and well appreciated, the communication of discharge letters and findings between different institutions is still mainly paper based [6].

Compared to other European countries the German health care system has a poor cost-benefit ratio which causes in connection with the impact of the demographic change and other related problems great further challenges [7]. The present situation is marked by over-, under- or inappropriate supply of health care services as well as the low patient centered orientation of care [8]. Despite general consensus about the importance of coordinated cross-sectoral cooperation in health care networks during increasing cost pressure and rising quality expectations, the required services are not yet area-wide implemented [6].

Due to the demographic change, there is a growing number of older citizens entail a growing number of chronic diseases and polymorbidity [8]. To allow adequate treatment for these kinds of complex diseases a lot of health care providers need to adjust with each other over a long period of time.

Various national and international eHealth projects have been started, with the aim to advance communication between providers in health care networks via information and communication technology (ICT). For example the European Union's project PICNIC (ProfessIonals and Citizens Network for Integrated Care) aim is to define the architecture for mainly flexible IT support delivered by exchangeable components [9],

[10]. An example for a national project is the health care region HealthCapital Berlin-Brandenburg [11]. In general the cooperation compounding of different care providers aims to extend beyond areas of activity, traditional boundaries of different specific disciplines and conventional structures. Furthermore the degree and speed of innovation will be specified by this cooperation [6]. The results of the broad mass of eHealth projects admittedly vary in quality and sustainability. Reasons could be the heterogeneity of the ICT landscape in the German health care system, missing business models to continue established networks, little user compliance as well as slow rethinking among the providers.

Against this background the project eHealth.Braunschweig was started in April 2009. The vision of all members, composed of care providers as well as representatives from science and economy, is the establishment of an interoperating, ICT supported, patient-centered health care network spanning all health care sectors in the region of Braunschweig and the surrounding neighborhood. The main idea of the project is: „Move the information not the patient".

By having a look at the following research questions the project should be effectively realized into practice and the results should have a lasting effect:

Q1: What regional distinctions does Braunschweig offer concerning the establishment of a local health care network supported by information technology?

Q2: What are the domain fields which have to be addressed for the development of a regional health care network and how can these domain fields be supported by modern information and communication technology?

Q3: What architectural challenges do regional health care networks face regarding defined requirements and addressed domain fields?

Materials and Methods

Our investigation is based on our previous work and experiences in the field of transinstitutional sensor-enhanced health information systems [5, 12-14] and integrated health care networks [15-18]. With regard to the respective literature we summarize the regional distinctions and the domain fields of our lately started regional network project eHealth.Braunschweig and then give an overview of architectural considerations for an inter-organizational information and communication platform which is part of the transinstitutional regional health information system. Finally we discuss the relevance of the project for the region and conclude with an outlook on future steps.

Results

Regional Distinctions

The need and effects of electronic communication in health care systems have been approved in many publications [2, 3, 6]. Through the use of information and communication technology (ICT) along the health care supply chain interruptions as well as delays in the workflow and media cracks could be reduced [19]. For instance by the use of electronic and online available discharge letters instead of paper-based discharge letters, which are often missing or incomplete. In this way the percentage rate of re-hospitalization could be reduced which also means a raise in quality of care while saving costs [6]. Based on the former demonstrated problems and future challenges for the German health care system different requirements for the establishment of a regional health care network supported by information technology were initially identified for the eHelath.Braunschweig project. While developing a regional IT- infrastructure for health care networks a wide variety of partly quickly changing economical, political, technical conditions have to be considered [20]. Most important for a well operating and accepted health care network are the specific user requirements and goals. First of all care providers and other shareholders concerned were compiled into collaboration within the eHalth.Braunschweig initiative. The most important participants on care givers side are the Medical Center Braunschweig, which represents the biggest care provider in the region, the German Red Cross (DRK) with representatives of nursing homes and mobile nursing services as well as the Association of Statutory Health Insurance Physicians Lower Saxony with several general practitioners and medical specialists. Further cooperation partners are the City Council of Braunschweig and the Public Health Department, different local house-building companies, the Council of Elderly People, several business companies and research institutions such as the Peter L. Reichertz Institute for Medical Informatics.

By realizing the ideas of eHealth.Braunschweig numerous advantages for participants are expected. In future care providers will benefit from the availability of relevant patient information spanning the entire network in the right place at the right time for the right person. Through the intensive cooperation with care providers new possibilities and innovations can be identified by the local business enterprise sector early. From this follows a head start for the local businesses which eventually results in competitive advantages for the region of Braunschweig. Because of great economic importance of the health care sector these advantages are leading to a multiplication at all levels of the chain in health care as well as public health or economy.

By identifying the requirements of the cooperation partners during several workshops the requirements for the establishment of a health care network were elaborated. The main problems identified by the care providers are e.g. an insufficient communication flow between different institutions in the region as well as poor coordination of care giving organizations along the health care supply chain. Based on these problems the major domain fields to establish a regional health care network will be specified next.

Domain Fields

Based on the project goals and previously described regional distinctions and requirements we identified our fields of activity which have to be addressed in order to achieve the

intention of the regional health care network eHealth.Braunschweig. The main goal of eHealth.Braunschweig is to establish seamless and patient centered health care in the region. This means vertical integration (across different health care sectors) and horizontal integration (across different specialization fields, indications and diseases) of health care processes and at the same time consideration of the patient in the main focus of every process. Therefore ways of information flow should be established and tightened in order to enable a continuous and barrier-free transmission of patient related information between different care givers. Taking into account organizational, functional, workflow-related, technical and financial aspects, we identified in our project different domain fields which depict in our opinion essential parts of inter-organizational communication and collaboration in a regional health care network. Identified domain fields will be described in the following section as main work packages which have already been started in the last month.

The first step towards inter-organizational communication is the establishment of a *consistent inter-organizational information standard* for the information exchange between different care givers (e.g. hospital (H), general practitioner (GP), medical specialist (MS), nursing home (NH) or mobile nursing service (NS)). Despite numerous efforts in the last decade, there is still no agreement in daily practice on a reasonable base data set or information set, which should be transferred e.g. from a general practitioner to the hospital along with hospital admission and back from the hospital to the following care provider after discharge. An information standard at this point should be determined bidirectional at least for the term of hospital admission (from GP/MS/NH/NS to the hospital) and discharge (from hospital to GP/MS/NH/NS). The base information set which should be made available electronically to different care givers, will contribute, in our view, to an effective and purposeful information flow especially at critical time points e.g. before weekend and should also help to reduce time-consuming telephone requests.

The next domain field describes the process-related definition of the *admission and discharge management* as a core part of transinstitutional health care management. Hospital admission and discharge are highly multifactorial activities in which different care giver professional groups inside and outside of the hospital as well as patient relatives are involved. Therefore a lot of problems e.g. delays or lack of information emerge at this point. At the same time as the base information set is specified in an inter-organizational information standard, the processes which are affected by this information should be aligned regarding a barrier-free information flow. This means that the target process definition should facilitate the availability of information and an easy access to it. Similar to the first step relevant processes need to be analyzed and target processes specified in a bidirectional way between care givers in primary and secondary care as well as nursing care and home care for elderly people.

The following domain field arising from the first two fields is the *workflow support* for transinstitutional medical, organizational and administrative processes within a regional health care network. The entire interaction regarding one treatment case at different points of care (e.g. GP, hospital or home care) including medical, organizational and administrative tasks requires workflow monitoring and control mechanisms. Adequate trigger mechanisms within inter-organizational information and communication processes which e.g. initiate the submission of patient data to a document portal after discharge or inform a GP about the discharge of his patient and the availability of documents could support the transinstitutional collaboration and workflows.

In order to support the inter-organizational collaboration tasks and workflows (described above) in a regional health care network via IT, the development and implementation of a *transinstitutional information and communication platform* depicts the next major domain field in the course of the project. Essential functionality of the platform will consist of services which interconnect the backend application systems of care giving network participants (GP or hospital) in order to extract and represent the required information of a patient problem-oriented and purposefully. Ideally system and data integration should be the main goal for the future which can only be achieved by standardization and semantic interoperability of the affected application systems. The next lower level of integration could be given by an architectural model involving web applications or web services which are interacting with each other and the backend applications. The information and communication platform should furthermore provide a role-based and secure access to the information through a web application, if there are no backend applications e.g. for patients, their relatives or also the mobile nursing services.

A fundamental part during the constitution of and operation within health care networks, which often fails into oblivion and does not get enough attention, is the domain field of *network management* and development of *sustainable business and financing models* for regional health care networks and for the continuing operation of the network after the termination of an eHealth project. Network management in a regional health care network comprises different management tasks – information management, patient and network participant administration, strategy definition, monitoring and control as well as controlling and reporting tasks. A major part of information management is the alignment of strategic goals of organizations and the corresponding information system architecture taking into account the specific characterization of health care networks e.g. non-hierarchical governance forms or collective vs. individual interests of network members [15]. In general health care networks can be characterized by means of the DIOGEN classification system along the five axes: network structure, network management system, medical care system, transinstitutional information system architecture and network phase [18].

A further substantial domain field of eHealth.Braunschweig, which differentiates this project from many others, is *intelligent home environment for elderly people* and the integration of sensor-enhanced health information systems into

regional health care networks, their health care processes and information system architectures [21]. Several apartments for elderly people owned by local house-building companies in Braunschweig are going to be prepared as age appropriate apartments for older people and additionally equipped with sensor-enhanced information technology (e.g. accelerometer, motion sensor, bathroom scale, ergometer etc.). The integrated technology helps to develop and provide new health care services (e.g. home monitoring) for older persons in order to support self-sufficient and self-determined life. The collected data should be preprocessed and supplied to the care givers in the regional health care network who are involved into treatment context of the patient or the older person [13], [21]. Other domain fields such as telehealth (e.g. video conferences or consultations), selective information providing concerning personal health and well-being (e.g. for elderly people), common multidisciplinary education and training portals for health care professionals are reasonable and could be integrated into the context of our eHealth project in future.

Architectural Challenges

Regional health information systems comprise health care environments in a certain region, e.g. including hospitals, offices of general practitioners, pharmacies, rehabilitation centers, or organizations for home care as defined in [22]. These information systems are characterized by mainly paper-based communication between the particular institutions even if there may be well established and successful used computer-based ICT infrastructure within one institution. The willingness to share information with other institutions usually depends on historically grown relationships and trustfulness between health care institutions as well as on availability of appropriate applications and their integration with the workflows of several institutions. Haux identified in [22] five current problems of regional health information systems which are the problem of obtaining referential integrity, information logistics problem, terminology problem, stability problem and information management problem. The regional health care networks which are part of the regional health information system are facing these problems when trying to introduce an inter-organizational information infrastructure to support the collaboration within the network.

The architectural challenges for the establishment of an inter-organizational information and communication platform within a regional health care network are still integration and interoperability between heterogeneous applications in different institutions, patient identification beyond institutional borders, workflow support between institutions and workflow adaptation of inter-organizational processes within institutions in order to support collaboration [23], [24]. Compliance with new inter-organizational workflows and processes should be supported and thus could be increased by adequate trigger mechanisms e.g. reminders. Integration of home telematics platforms and sensor-enhanced data with health information systems and applications of health care providers is a major challenge in the context of regional medical and social networks. More services of telemonitoring, telehealth or personal health records will be available in future to the patients and elderly people and thereby more data could be collected and preprocessed by the patient. Therefore the institution *patients' home environment* should be also considered as an important institution within the regional health care network [22]. These architectural considerations should certainly be made with regard to data safety and security which are basic requirements in a distributed information and communication infrastructure dealing with sensible patient data.

Discussion

The importance of inter-organizational collaboration and positive effects of information processing in regional health care networks have often been pointed out and partly found realization in regional projects of integrated care networks. Nevertheless the core problems of integration and interoperability as well as workflow support are still existent and there is a lack of introduction of new solutions into daily health care practice. In our regional health care network eHealth.Braunschweig we aim to work on the described domain fields in cooperation with network members from all organizations in order to identify substantial relevant and significant collaboration tasks, to develop applications to support these tasks and to evolve sustainable and lasting information system architectures which will be embedded into the regional health information system and infrastructure. Our goal is to establish inter-organizational health care processes which support and help the care givers in their daily work, to facilitate easier information exchange and reduce the time spent on data searching and request.

Conclusion

We identified the regional distinctions and requirements for regional health care networks and because of that depicted in our opinion the most important domain fields which should be dealt with in a regional eHealth project. The domain fields were identified as follows: consistent inter-organizational information standard, admission and discharge management, workflow support, transinstitutional information and communication platform, network management, development of sustainable business and financing models and intelligent home environments for elderly people. We also highlighted architectural challenges for the establishment of an inter-organizational information and communication platform within a regional health care network regarding the addressed domain fields. Our future work will concentrate on process analysis, inter-organizational process definition and information standards as well as design and development of a prototype system which can be deployed in the health care network and evaluated by network members.

A countrywide clinical informatics project in Uruguay

Alvaro Margolis, Lino Bessonart, Ana Barbiel, Pablo Pazos, Juan Gil, Heber Machado, Alvaro Vero

Federación Médica del Interior, Montevideo, Uruguay

Abstract

FEMI is a federation of 23 private not-for-profit health care organizations across Uruguay. It covers approximately 700 thousand people (20 percent of the Uruguayan population) and owns a tertiary center in Montevideo. Pressure from ongoing national changes in health funding and regulation have pushed FEMI to develop a project, in order to improve efficiency in health care through the use of information and communications technologies. In particular, a federal electronic health record and a strategic management system are pursued. This project is supported by the Inter American Development Bank. The project has four lines of action: Specification, construction and implementation of the systems; Alignment through the use of standards; Cultural change through training and prototype systems; and Infrastructure. Short term results include a federal balanced scorecard, federal identification and authorization services, a terminology service, telemedicine applications and massive training of interdisciplinary teams at the local level. The importance of collaboration at the regional level and the advantages of having a multi-institutional commitment are stressed.

Keywords:

Uruguay, South America, Information systems, Computerized medical record systems, Inservice training

Introduction

Uruguay is a small country located in the southern cone of South America, with 3.4 million people, half of them living in Montevideo. Its health indicators (e.g., life expectancy of 76.6 years, infant mortality rate of 11.9 deaths / thousand) are close to those of developed economies. The health care system is comprised of public and private not-for-profit organizations. The latter cover approximately 60% of the population and are HMO-type organizations, providing both insurance and health care. There is an on-going health care reform, designed to increase coverage and improve management of the first level of health care.

FEMI (www.femi.com.uy) is a federation of 23 private not-for-profit organizations across Uruguay. It covers approximately 700 thousand people, owns a tertiary referral center in Montevideo, over 30 hospitals with 1500 beds and 100 outpatient clinics across the country, and 2800 physicians work there. Three-quarters of its budget comes from the National Health Fund, administered by the Social Security.

Pressure from ongoing national changes in health funding and regulation have pushed FEMI to develop a project, in order to improve efficiency in health care through the use of information and communications technologies (ICT). This project is supported by the Inter American Development Bank through the MIF Fund, and by the Secretary of Health. It aims at the exchange and analysis of administrative and particularly clinical information at a federal level, taking into account the different levels of information system development of each individual institution of FEMI. The project was officially launched in March 2008 and has a four-year duration.

A previous publication [1] has shown the massive training strategy across the country during 2008, in agreement with a more general conception for developing countries [2]. In this paper, a description of the main lines of action and short-term results, and an update of the training efforts are shown.

The project

The project needed to consider the different levels of information system development across the Federation, as shown in the survey performed across it: While all of the institutions have the administrative systems necessary for the day-to-day operations, and the majority have some kind of departmental clinical system in place, most of them don't have comprehensive electronic health records. There currently are about 2500 PCs and 100 servers across the Federation.

Furthermore, each Institution within the Federation was free to choose the information technology vendors, so there are a variety of systems in place, although two vendors cover half of the institutions. The project also intended to provide federal functionalities while accepting autonomy, and legacy administrative and departmental systems of each institution. A general diagram of the proposed system architecture is shown in Figure 1. The main lines of action in order to achieve the above results are shown in Figure 2.

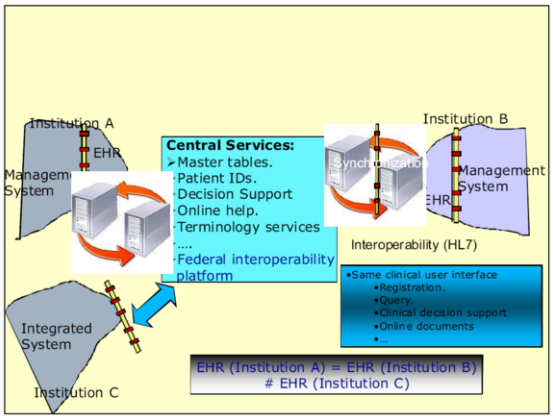

Figure 1- Model of the federal electronic health record.

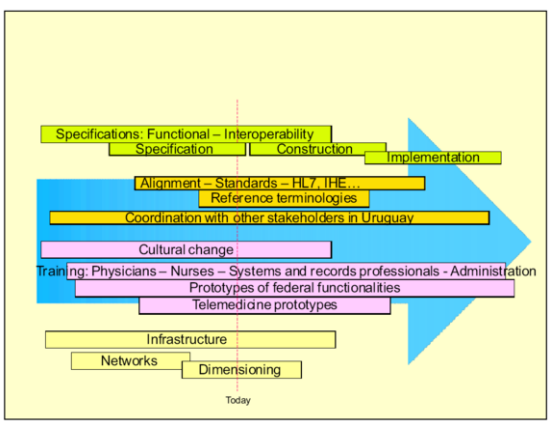

Figure 2- Main lines of action at the FEMI Project.

The first line of action, *Specifications*, includes the Specification itself, Construction and Implementation of the Federal Electronic Health Record (EHR). The EHR will be implemented in the Emergency rooms and later in the outpatient settings in five pilot institutions during a first phase, and in the rest of the institutions in a second phase. Most other components involve all of the FEMI institutions from the beginning. This line of action also includes the design and construction of a balanced scorecard (a strategic performance management tool).

The second line of action, *Alignment*, includes the 1) use of standards for information exchange and representation (for example: messaging standards, standard terminologies, federal identification services), and 2) coordination with other stakeholders in Uruguay (Secretary of Health, Social Security, HL7 Uruguay, other health care organizations).

The third line of action, *Cultural Change*, includes 1) Training, 2) Prototypes of federal functionalities, such as the Federal Authorization Services, and 3) Telemedicine, where Telemedicine applications are used as a rather quick way to bring health care professionals into the use of information technology and into the Project.

The fourth line of action, *Infrastructure*, includes Computer and Videoconferencing Hardware, Software and Networks.

Results

In this section, the short term goals and achievements already realized or expected before March 2010 are discussed, in the context of the overall project.

There is a crossover among the lines of action. For example, the federal identification service is related to *Cultural Change* and to *Alignment* and is a requirement for the federal electronic record explained in line 1; and the telemedicine applications needed the Intranet – *Infrastructure* - to be updated.

Specification, Construction and Implementation

Regarding this line of action, a **federal balanced scorecard** will be implemented before the end of 2009, after having finished the selection process of the consulting firm. Each institution will have available their indicators from the National Indicators System SINADI and other clinical performance data, compared historically to themselves and to the rest of FEMI Institutions.

Regarding the specifications of the **Federal Electronic Health Record System**, KPMG Consulting firm has just finished the Specification, and next steps (construction/adaptation and implementation) are to begin.

In parallel, there is a **process redesign in clinical areas** where the electronic health record will be implemented (particularly Emergency room and ambulatory settings), with the help of Hospital Italiano de Buenos Aires.

Alignment

In this chapter, the advancements in identification and terminology services are shown. There also is a national consensus to use HL7 CDA as a messaging standard. These and other topics are being discussed in periodic meetings with the other main stakeholders in Uruguay (Secretary of Health, Social Security, HL7 Uruguay, and other health care organizations), since the alignment includes organizations external to FEMI.

Identification services

The provision of identification services in order to identify a person unequivocally is a foundation for the federal record system and other federal applications, as disparate electronic systems need to link personal information across institutions with the lowest chance of error. This service also needs to take into account the legislation regarding personal data, which has

recently been passed and applies to every health care organization and to the federation as a whole.

In Uruguay, there is a national identity number that exists from birth. Nevertheless, a series of patient data needs to be taken into account to ensure that a proper match among existing records within the federation is being done, because no single patient identification number is considered to be sufficiently reliable or universal [3]. That is why the goal is to implement an identification service instead of trying to look for the best unique identification number [4].

This service cannot be successfully implemented unless the different processes involved in identifying patients are carefully reviewed. The main processes involved are: Registration, accreditation and audit. *Registration* is the process through which each Institution assigns a personal identifier and registers it along with his/her personal data, in order to be able to carry out a correct accreditation at a later moment. *Accreditation* is the process through which each person is verified to be the person who claims to be, and consists in taking the personal data given by a person and then compare them with the data registered in the previous process. These processes depend on the quality of the information registered in the organizational systems. For example, if the registration process has an error, the accreditation process will be affected. For this reason, there is an *auditing* process, where the registered data are verified for completion and accuracy. If all the information registered is verified, then the accreditation process could be performed in an optimal way. To help in the auditing process, the records could be marked in different states, such as: temporal, permanent or validated. The "temporal" state means that the record was not verified as complete or correct. The "permanent" state means that the record is complete but was not validated as correct. The "validated" state indicates that the record is complete and correct.

The process followed to obtain the identification service at FEMI was developed in several stages. First, there was a survey to understand what data were registered for FEMI patients and to detect problems in registration and also possible incompatibilities among different institutions which could lead to problems in the future, when attempting to share clinical information. The main problems detected were under-registration (to register less data than necessary for a correct identification), and the formats of some fields, such as date and codes for gender. This survey was carried out in 13 of the 23 institutions, and the rest of the institutions will be surveyed before the end of 2009. In a parallel work, there is coordination with the Social Security and the Public Health Services, to use similar identification data sets and algorithms.

The federal identification service is currently being implemented, with the goal of not only identifying persons, but also to offer related services, such as coverage for each patient, and geo-referenciation of patients' homes and workplaces, as well as physicians' offices.

The federal identification service is a key element to implement other federal services, such as sharing of clinical documents among institutions.

Terminology services

The use of natural language simplifies the registration requirements in the EHR for health care providers, but limits the reusability of the data, except for patient care. If, at the same time, specific fields are coded automatically from natural language strings, the best breed is achieved. This is one of the main reasons for using a Terminology Service. Through this service, a terminology is used as a reference (for example, SNOMED CT) and then it is related to the natural language used in the country or region. Classifications are used as output vocabularies (such as ICD-10, CPT, DRG) for reports and analysis [5].

To obtain this product, an adaptation of the medical terminology service developed at Hospital Italiano de Buenos Aires [6] was decided. This service uses international standards, and will take into consideration the needs of FEMI and other Uruguayan institutions. A match of over 80% is expected from Argentinean to Uruguayan natural medical language as a starting point for the service, considering the experience between Argentina and Chile [7].

The use of standards is a fundamental component of the Project. The Terminology Service will allow to represent clinical data mapped to different standard classifications, increase the analytical capabilities of data registered in FEMI systems, allow the exchange of information across institutions within and outside FEMI, and eventually implement decision support systems.

At this time, an agreement with Hospital Italiano de Buenos Aires has been reached, and the first trials are being made. A note should be made that current FEMI systems could use the Terminology Services, without the need to wait until the Federal Health Record is in place.

Cultural Change

Cultural change is a main line of action of the Project, as success largely depends on it. It involves hundreds of professionals at local governing boards and technical coordinating teams across 23 institutions, as well as eventually 2800 physicians and more than ten thousand health and administrative personnel. A more professional strategy is being finalized with the help of communication and organizational change specialists, but – in the meanwhile – the project coordinating team has devised several change management strategies, including training, implementation of system prototypes and telemedicine applications, described below.

Training

A great effort has been made to train local interdisciplinary units, as shown in [1]. An update of these results shows that:

- The 10 x 10 introductory online course on health information systems (approximately 150 hours of coursework), developed by AMIA and adapted for

the region, was taken by 72 professionals in its 2008 and 2009 editions.

- The face-to-face introductory course developed in conjunction with the Uruguayan Health Informatics Society SUIS was taken by 85 professionals in its 2008 and 2009 editions.
- The HL7 online course was taken by 40 informatics professionals in its 2008 edition.
- Sixty-seven nurses in coordination roles from across the country participated in the Nursing Informatics and Quality Conference in March 2009.

Now an end-user training strategy is being designed and implemented, considering the massive training needed and that the deployment times will differ across institutions. First, a *survey* to understand end-user basic and health-related informatics literacy has been designed and is being implemented in pilot institutions. Then, three levels of training will occur: 1) *Basic informatics training* for those who need it (which will rely on local organizations). 2) *Concepts about the Electronic Health Record*. This is intended as a change management tool for health care providers, designed to change attitudes and provide basic knowledge about the topic. The methodology is train-the-trainers, where the ones providing the actual training will be the local coordinating units, because they will then become the local experts for the end-users regarding the new system being implemented. The first courses on Concepts about the EHR will be at the beginning of 2010. 3) A more *skills- and processes-oriented training* just before the implementation of each module will be provided as needed, blending professionals from the consulting firm in charge of the EHR, the central unit and the local units.

Authorization service

A by-product of the federal identification service, which has been needed for a long time in FEMI, is the authorization service. This service will allow a patient from one FEMI institution to go to another institution and be authorized though a semi-automatic and documented process. It is a change management strategy at the management level, because a short term result is shown while waiting for longer term goals.

Telemedicine applications

At the other end of the spectrum, telemedicine applications are viewed as a way of integrating technology for the end user. A plan has been designed, including continuing health education, then tele-rounds and finally tele-consultations (without and with the EHR). The first continuing education events are being carried out. As an example, in September 2009, about 700 health care professionals in 20 sites participated in an educational event about type 2 diabetes, with the use of tele-confererencing technology. Small-group discussion was included in the methodology (78 small groups reported back), and the final plenary with the experts took into account the small group reports, integrated automatically via Google forms.

Infrastructure

FEMI has a national intranet that has been expanded to take into account the new requirements, including high quality live videoconferencing.

Discussion

There are some topics that come across the different lines of action of the project. One of them is the **added value of having a federal project**: 1) there are functionalities that involve the whole federation and not each one of the institutions (for example, the authorization service, and distance continuing health education events or tele-consultations); 2) there is an economy of scale in working together in a project (for example, in change management and training, or in having some services at the federal level, such as the terminology services); 3) it is possible to do things that otherwise would not be possible, such as negotiating with the other main stakeholders, having the advise of recognized international academic institutions, or having a centralized highly specialized coordinating unit.

The other topic is **international south-south collaboration**, particularly with Hospital Italiano de Buenos Aires, in distance health informatics training, terminology services, and consulting. But other organizations or experts from abroad have also helped in nursing informatics training (Brazil and Argentina), Telemedicine applications (Switzerland and Argentina), and HL7 (HL7 Argentina), as well as in the overall project strategy (Chile, Argentina and others).

Conclusion

This ambitious project intends to integrate 23 institutions across Uruguay, using the electronic health record and management tools. The first stages of change management and alignment have been successful, but there still is a long way to go in order to achieve the main results.

Acknowledgments

This project is partially funded by the Inter American Development Bank, through its Multilateral Innovation Fund (http://www.iadb.org), project UR-M1021, “Productivity and Management Improvements in Healthcare System”.

We acknowledge the help of Ms. Magdalena Hourcade and Ms. Alejandra Melgarejo in gathering the data for this article. We would also like to specially thank the academic institutions, SUIS, Hospital Italiano de Buenos Aires and HL7 Argentina, which made this training possible, as well as the site visits to Hospital Austral in Argentina and Instituto de Seguridad Social in Uruguay.

Abstract

In an environment of expanding demand on the health care system to provide equitable, accessible and safe health care, usage of information communication technology is one of the strategies identified to fulfil such expectations. Electronic Health Record (EHR) is an important tool towards achieving better health care using such technology, although, across the world EHR implementation has experienced a high failure rate. Nevertheless South Africa has made a strategic decision to implement EHR system in the public health sector. An evaluation toolkit was developed, to measure the state of readiness of health institutions in South Africa in implementing EHR based on Kaplan and Norton's work on Balanced Score Card (BSC), and the subsequent variant model developed by Protti. A Critical Success Factor (CSF) scorecard to assess the state of readiness and a Balanced Score Card matrix to be used as a strategic framework was developed. These tools were validated using critiques by a panel of experts. The toolkit developed has the potential to assist the organization towards a better EHR implementation path.

Keywords:

BSC, Balanced Score Card, Evaluation, EHR Implementation, Critical Success Factors

Introduction

South Africa is a developing country consisting of vast rural areas. The South African Health Care System consists of public and private health sectors. The Public Health sector caters for 82% of the population, and accounts for 40% of health expenditure. The balance of the population (18%) is served by the private sector, which enjoys 60% of the health expenditure. The public sector is funded and provided for by the state through its National and Provincial Department of Health (DOH). Health services are free at the point of delivery in the primary health care facilities. The secondary and tertiary levels of health services are provided for a nominal payment, based on each individual's income. However, vulnerable populations such as children (under 18years), elderly (over 60 years), pregnant mothers, and patients suffering from conditions like Human Immunodeficiency Virus (HIV) infection, tuberculosis and epilepsy and so on, receive free health services, even at the secondary and tertiary levels.

The country is inundated with inequitable health service delivery between its rich and poor, as well as rural and urban populations. The use of technology is hoped to improve the quality of health services, as well as reduce the inequality between rural and urban health service delivery.

Although advanced Information Communication Technology is available in many urban healthcare institutions, most rural facilities do not even have computer technology. On the other hand, even though the telephone infrastructure is lacking in rural parts, mobile phone technology (e.g. 3G technologies) is widely used across the country.

The potential benefits of the EHR system (better, safer and equitable health care) are well known,[1-3] but more than 50% of the information systems either fail, or fail to be utilized to their full capacity.[4,5] Even among developed countries, the degree of adoption of EHR varies largely.[5] Lessons learned from the past caution us about the barriers and challenges facing EHR implementation projects in healthcare institutions.

Many models [5-9] have been presented by researchers for the successful implementation of information systems in healthcare sector. However, none of them is a readymade solution to the problem, as implementation is highly dependent on the context of the organization, with its technology, people and organisational issues. The degree of adoption of EHR is difficult to predict, as it has been shown that different organisations, and different units within one organisation, adopt some functionality of the EHR better. [10]

Healthcare organisations are complex due to the fact that various units, divisions, people, sectors and technology, all work together to reach an objective. In complex organisations, the poor performance of one area, affects the performance of the other areas, essentially giving rise to the snow ball effect. Therefore, complex healthcare organisations present huge people, and organisational, issues in the quest to change from paper to EHR. [11]

More and more emphasis is put on the need to address the people and organisational issues for achieving success. [12-17] The EHR should not be seen as a technological issue, but rather as a socio-technological one.[15] The emphasis is on the requirement for the technology to change to adapt people's work flow, and the people to adapt to a different way of work-

ing to adopt the technology. Success will be difficult without this 'fit'.

The aim of the project was to illustrate a way to maximize the chances of success in the envisaged National EHR implementation project in South Africa. The objective was to develop a toolkit to assess the state of readiness of health organisations in South Africa to implement EHR. In order to fulfil this objective, two instruments have been developed based on Kaplan and Norton's work on Balanced Score Card (BSC), and the subsequent variant model developed by Protti.; first, a critical success factor (CSF) scorecard, and the other, a strategic planning and management framework matrix.

Critical Success Factors Scorecard

Critical success factors (CSF) are defined as the limited number of areas in which satisfactory results will ensure successful competitive performance. [18] The CSF come from the areas of hardware, software and the people and organisational issues. In this paper the CSF used by Protti [19] for the assessment of the state of readiness to implement Information for Health in the National Health Service in the United Kingdom was identified as the baseline instrument. This baseline CSF list was modified for two reasons. Firstly, the structure of the health system of the United Kingdom is different from the South African health system, and secondly the experience from the past EHR implementation projects highlights the need for addressing the people and organisational issues among the CSF.

There are eleven CSF identified for the CSF scorecard. Each of these CSF is described below.

Clinical initiative linkage: Protti claims that explicit linkage of EHR project implementation to clinical services and clinical governance is important for success.[19[The IT strategy (EHR) should be part of the organisational strategy in order for it to be successful.[20] Only then can the organisational strategy influence the IT, which in turn can influence the organisation, as an isolated EHR project will be neither successful nor sustainable.

Clinician involvement: Involvement of clinicians (doctors, nurses, pharmacists etc.) is an essential factor to ensure success.[21,22] The involvement and participation of clinicians in the process allows for the EHR to be designed /modified to fit local needs, and develop a sense of ownership by the users. This will further assist in the system gaining acceptance.

Stakeholder involvement: All stakeholders need to be actively involved in the process of EHR implementation. The involvement of top management is always critical for success. The IT section and their support services also need to be part of this process in order for these divisions to understand the clinical work process, which will ensure that the technology fulfill the user's expectations.

The involvement of the community through various structures (hospital board, Non Governmental Organization, patient interest groups) is also equally important as a means to get the public corporation as transparency of process and access to information are people's constitutional rights. Participation from community representatives will provide the community with an opportunity to understand the rationale of the system and to raise any concerns (e.g. issues surrounding confidentiality etc). This understanding and participation enable easier acceptance of the EHR. Therefore the participation of all stakeholders at the EHR implementation committee is essential to maximize success.

Investment strategy: There is a need to have a clear commitment in terms of the budget allocation from national, provincial and institutional levels, along with a clear spending process in place at the facility. There is a need to ring fence the budget for the EHR implementation, and to appropriately budget for the future IT infrastructure, considering the available facilities. This will facilitate the sustainability and the success of the project. [23]

Local vision: It is important to have a clear local vision regarding the EHR project, as it is this that informs people of the ultimate goal. In addition, the organisation must identify local issues and recognize barriers to the implementation of the project to enable them for intervention.

Information management: The benefit of an Information System is dependent on its data quality. Hence, the establishment of processes to address data quality issues is critical.[19] Maximizing the data quality at all levels should be an active part of the project implementation.

EHR Implementation committee: An established EHR implementation committee with Chief Executive or an equivalent as chair for the project is mandatory.[19] The use of a 'consultant' to chair the committee will not derive adequate support from the employees, and will not be sustainable in the long run. The committee should be able to anticipate and influence requests from both end users and management.

Project management leadership: Having an experienced project manager in a full time post (someone who will move the agenda forward with minimal dependency on management consultants) is crucial for success and sustainability. [24]

Technical infrastructure: The organisation must have a thorough understanding of the types, costs, standards and plans for all IT systems, as well as a strategy for future development. The dynamic development of hardware and software in the IT field makes the understanding of IT systems, and its applications, vital for success. This ongoing development result in additional expenditure for the organisation and the health community needs to have the capacity to manage this as part of the future development.

Human resource: Comprehensive assessment of the required Information Management Technology personnel types, skill levels, etc, is very important, as a lack thereof will directly impact on the project implementation. It is understood that within the life cycle of an organisation new personnel join, even as others leave, and there should be a process in place to assess and train staff with the future in mind.[25] Developing a culture of 'sharing knowledge' among employees will ensure that the organisational knowledge base is adequate at all times.

Thus, knowledge management should be a key strategy in the EHR implementation project.

Change management: Protti, in 1999, did not include "change management" as one of the CSF. However, he discussed the importance of 'change management' and 'culture' as risk factors in his report. The experience from the failed IT projects in the past two decades, and the attribution of the implementation failure to people and organisational issues warranted the inclusion of change management in the CSF score card.

The heightened focus on the socio-technical approach of information system implementation further support this. There should be clear and established strategy and process in place to manage change in the organisation as well the technology Therefore it is vital to have an accepted change process in place. Change management should have multiple strategies to achieve the desired change, both in people and the organisation.

Nine out of the 11CSF from Protti's Model remained the same in the SA version. However, LIS Programme board was replaced by EHR Implementation committee. This was due to the difference in the basic administrative structure between the South African and the United Kingdom's health systems. The CSF of supporting the General Practitioners Practices, Primary Care Groups and PCTs was removed and change management was included as it covered a broader area of support during the implementation.

The CSF scorecard should be completed by the project manager/Chief Executive Officer/ Officer in charge along with IT person in-charge. The instrument can also be completed by the project committee members to obtain an overall sense. The organisations which fell short can go through the exercise at a later stage and re-evaluate their state of readiness.

Scoring: Each CSF is scored on a scale of zero to three. On this scale, a score of three implies that that particular CSF is 'fully in place' according to the definition of the CSF, and zero implies it is not in place at all. A score of one is close to not ready (zero), and a score of two is close to being ready (three). Any CSF scoring zero or one is taken as falling critically short in the preparation process of EHR implementation. It indicates that the situation needs urgent attention and serious intervention to rectify the shortfall. The choice of 0-3 as the score was selected to avoid a neutral number being the midpoint such as 1-5. This is to ensure that a decision is made as to whether the CSF is in a state of readiness or not. [19]

Scoring by numbers should be taken as an indicator rather than absolute, as this exercise aims to identify the organisation's state of readiness before implementing the project. The CSF scorecard allows a maximum score of thirty three (11 factors x3). If an institution scores less than sixteen overall, then it should be expected that in order to achieve successful implementation, a great amount of work is needed in the organisation. [19]

It is also important to avoid situations where the total score may be more than sixteen, but in which some of the critical success factors are scoring zero or one. In a complex system like health care, the performance of one critical factor influences the others, either positively or otherwise and the importance of the interrelationship between the factors needs recognition. Achieving a balance among the factors is as equally vital as their individual performance.

BSC - Strategic Planning and Management Framework

Table 1 – BSC four perspectives

User perspective *(Customers' & stakeholder's view)*	***Business value perspective*** *(DoH view)*
Mission To add value to health service delivery **Key Question** Would the EHR fulfill the needs of the clinical community? **Objectives** Establish good relationship with the user community (clinicians) Clinician Involvement Satisfy end users of EHR Clinical Initiative Linkage Stakeholder Involvement	**Mission** To add value to the SA Health System **Key Question** Would the EHR implementation accomplish its goal and contributing value to the South African Health System? **Objectives** Ensure that the proposed EHR project provide business value to the health system Local Vision Control EHR project costs Investment Strategy
Internal operations perspective *(process based view)* **Mission** Implement EHR project in an efficient and effective manner **Key Question** Would the EHR project be implemented in an efficient manner? **Objectives** Anticipate and influence requests from end users and management EHR Implementation Committee Provide cost effective training that satisfies end- users and ensures data quality Information Management Effectively manage EHR related problems that arise Project Management Leadership	**Future readiness perspective (***Innovation and learning view*) **Mission** Deliver continuous improvement in the EHR and prepare for future challenges **Key Questions** Is the EHR implementation prepared for potential changes and challenges? **Objectives** Anticipate, prepare and act on EHR related changes needed in the future Change Management Continuous upgrading of skills through appropriate training and development Human Resource Conduct research into emergin technologies for the SA health system Technical Infrastructure

The Balanced Score Card (BSC) is an instrument meant to assist organisations in proactively planning their performance

in line with the organisational strategy, rather than evaluate the organisation on its performance as a retrospective exercise. [26, 27].The original BSC was developed for the corporate sector, and thus the perspectives were designed with terminology to suit the corporate scenario.

Protti, for his work with National Health Services, modified the original BSC with appropriate terminology of the perspectives to better suit the context and the purpose of health institutions as 'Four Possible Perspectives in an Information Management and Technology' for health. The authors use Protti's terminology with some modifications in order to better suit the context of the South African health system. [19]

The purpose of this tool as a strategic planning and management framework is to assist health organizations in strategically planning for the implementation of EHR, and then later assessing and reviewing their performance according to their strategic goals. At this juncture, the framework will be used as an instrument to systematically work on their strategy, with the intension to improve or enhance the performance, taking into consideration the four different perspectives.

Following the concept of the BSC as a performance management tool, and the importance of the relationship of the perspectives to each other, the CSF were packaged into one of the four perspectives. The placement of the CSF in different perspectives allows one to understand the importance of the CSF against the backdrop of the total performance of the organisation, as well as the interdependence of the factors. The CSF can thus be easily linked to the specific strategic goal, and be followed up. The CSF in different perspectives also allows one to look at the balance among the different factors in each perspective, a vital component for success.

It will also allow the health organisations to align their objectives in different perspectives to achieve their vision, as well as enhance the performance of the other perspective. Mapping the strategy of the organisation in this manner will also create a common understanding among the employees. [28] The tool will act as a transparent strategic framework for all the employees in the organisation, and may yield better cooperation and understanding towards EHR implementation. It is hoped that developing a visible common objective will benefit the organisational culture in acknowledging and accepting change with less resistance.

Validation of the Assessment Toolkit

The development process of the assessment toolkit included a validation process. A panel of international and national experts critiqued the instrument related to its theoretical underpinning, content and format. There was a general consensus from the experts that the proposed toolkit to be an important development, as there is a need for such an instrument. They also found that the timing of the development of the toolkit was appropriate in the context of South African EHR policy and implementation process.

The selection of the CSF was found to be both relevant and appropriate, with the inclusion of change management to the CSF seen as necessary. The BSC theory of looking at the performance of the organization through four different perspectives (modified by Protti) was accepted as relevant and appropriate. The experts agreed that the critical success factor score card would be able to provide valuable information about the state of readiness of the institutions, whilst the four perspective matrix would assist the institutions in identifying shortfalls within the perspectives, and in developing interventions towards achieving the strategic goals of the implementation project. The matrix also provides insight into the future performance of the organisation.

The experts were of the opinion that the toolkit had the potential to contribute positively towards the successful implementation of EHR in South Africa.

As part of the validation a pilot study was conducted on priority ranking and weighting of the CSF by health workers. Clinicians' involvement and investment strategies were two of the CSF scored highly by the health workers. The study showed that the importance placed on the CSF by doctors and nurses were different and probably based on their workflow. Further, the importance given by the health workers to the four perspective matrixes, (BSC) was not equal in that health workers did not consider the business perspective as important as the other three perspectives. The survey showed that there was correlation between the ranking and weighting of the CSF.

From the information gathered from this pilot study, it is recommended that a full scale study is needed to understand the health professionals views regarding the CSF, workflow and other issues related to EHR implementation.

The tools developed in this study integrate the CSF with the Balanced Score Card matrix. Therefore the state of readiness assessment, the strategic planning of the implementation as well as the future assessment of the implementation will be a continuum rather than three unlinked exercises. It will assist the planners, managers and the health workers to see the interdependency between the CSF and BSC.

In conclusion the toolkit developed to assess the state of readiness of health organizations in South Arica to implement EHR has the potential to assist the organisation towards a better EHR implementation path. The second tool of BSC matrix will further guide them in moving the strategy to action plan and increase the probability of success.

A future study in the Eastern Cape is planned for a real world testing and validation of both instruments developed in this study.

Acknowledgments

The authors would like to thank all those who kindly spent time to comment on the draft tool and CSF's, the members of the expert panel and the health workers who participated in the pilot study.

Abstract

In African countries, communicable diseases remain the chief cause of a heavy disease burden. Regional economic, political and social integration bring new challenges in the management of these diseases, many of which are treatable. Information Communication Technology (ICT) applied through electronic health systems has the potential to strengthen healthcare service delivery and disease surveillance within these countries. This paper discusses the importance of well-defined e-Health strategies within countries and, in addition, proposes that countries within regions collaborate in planning for health information exchange across borders. It is suggested that particular attention be paid to technical and data standards enabling interoperability, and also to issues of security, patient privacy and governance.

Keywords:

Health information systems, Electronic health records, Standards, Medical records.

Introduction

In many regions across the globe the 21st Century is witnessing an increase of economic, political, and social integration. Some refer to it as the Globalization of this century. In Africa, the regional organizations formed in response to this are guided by political and economic treaties and policies. These organizations include the Southern African Development Community (SADC) and the Common Market of East and Southern Africa (COMESA). A consequence of this economic and political integration is increased cross-border movement of people within the regions of the Member States (MS) included in these treaties. Besides sharing common social and cultural values, the MS also share common health challenges threatening the livelihood of the region's population. In most regions of Sub-Saharan Africa communicable diseases especially Human Immuno Deficiency Virus (HIV) and the resultant Acquired Immuno Deficiency Syndrome (AIDS), Tuberculosis (TB) and Malaria pose the greatest threat to the well-being of the population.

The increase of population movement across MS means changes in the dynamics of communicable diseases. A typical recent scenario was the deadly outbreak of cholera that started in Zimbabwe in the month of August 2008 [1]. By the end of 2008, the disease had been reported in four neighbouring countries: Botswana, South Africa, Mozambique and Zambia. Cases were also reported as far afield as Katanga, the southernmost province of the Democratic Republic of Congo [2]. This is an illustration of a classical case that clearly highlights the need for regional health information exchange of medical and health data between neighbouring countries or regional MS. Many neighbouring countries and regional MS collectively appreciate the scourge of communicable diseases and have pledged to actively participate in the control of these diseases through declarations and protocols at national, regional, continental and international levels. Fundamental to the control of these diseases has been the pledge to share health information for the common goal of controlling these diseases across MS. Real examples of these in Africa include:

- The Abuja Call (May 2006) for Accelerated Action Towards Universal Access to HIV and AIDS, Tuberculosis and Malaria Services in Africa in which African Union MS pledged, among other issues, to ***strengthen data management and surveillance systems*** of each of these diseases.
- SADC Protocol on Health in which MS pledged, among other issues, to ***standardize regional disease surveillance systems*** to facilitate collation of information which has a regional impact.

As cross-border movement increases and the ensuing spread of diseases presents more of a threat, it becomes critical that regionally integrative health information systems are made a core component of any regional economic and political initiatives. This will facilitate the flow of critical information and knowledge across borders to enable the delivery of safe healthcare services, the continuity of patient care and the effective monitoring of diseases across borders.

Health Information Systems & eHealth

At the fifty-eight session of the World Health Assembly (WHA) in May 2005, delegates adopted a resolution to establish an eHealth strategy for the World Health Organization (WHO), indicating that there is urgency for MS to have well-planned eHealth services for their respective countries. The main rationale for this strategy is derived from the potential for Information Communication Technology (ICT) to transform healthcare service delivery. ICT has had a profound impact on many aspects of human development such as banking, commerce and communication. ICTs enable information sharing across geo-political boundaries, providing opportunities for co-operative development in many areas, including healthcare. Despite this, the uptake of ICTs in healthcare has been relatively slow and less progressive than in other sectors of modern society. The use of ICTs in health is broad and diverse. It ranges from population based record systems that monitor disease trends, through electronic surveillance systems which capture patient related data for health care or administrative purposes, to patient-based electronic medical record systems. Electronic Medical Record (EMR) systems improve the quality of care by "improvement in legibility of clinical notes, decision support of drug ordering including allergy warning and drug incompatibilities, warning for abnormal laboratory results, support for program monitoring, including reporting outcomes, budgets and supplies, support clinical research and management of chronic diseases such as diabetes, hypertension and heart disease" [13] . Furthermore, the access to accurate and precise information by healthcare service providers reduces medical errors, reduces duplication of data entries, and strengthens decision support tools within a health system [14]. Electronic information systems within a specific area of health such as public health disease surveillance systems enhance the response intervention times to disease outbreaks such as cholera. Through disease surveillance systems, coupled with Geographic Information Systems (GIS), it is possible to effectively monitor disease spread spatially and implement coordinated and appropriate control measures based on real time data access.

Electronic health information systems, used either for patient care delivery or population based disease surveillance, have the potential to support the exchange and transfer of health information across borders. It can strengthen the cross-border continuation of patient care in chronic cases like antiretroviral therapy for HIV and AIDS patients. It can also strengthen regional capacity to mobilize resources and respond collectively to disease outbreaks, such as the outbreak of cholera experienced in Zimbabwe in 2008.

A collaborative regional eHealth Strategy can provide the framework for building and implementing health information systems in a coordinated way that allows for regional integration. It is vitally important that developing countries develop such a strategy as early as possible to avoid the risk of overspending and the heavy costs incurred in systems adoption and reengineering.

Challenges & Opportunities

Health care providers and policy makers in developing countries are daily faced with the challenge of making decisions that allow them to get the most out of scarce resources. The efficient resource utilization they seek is characterized by:

- Little or no wastage of resources.
- Provision of quality tools for healthcare providers despite limited market availability.
- Provision of real solutions addressing the health priorities of the population and communities.
- Delivery of healthcare services at the lowest cost while adhering to safe care protocols.
- Providing healthcare services to vulnerable communities despite time constraints and the shortage of healthcare professionals.

Meeting these requirements would have a positive impact on the quality of services that health systems can deliver to their communities in a timely manner. In reality, the healthcare needs of populations in developing countries remain actively unmet due the challenges faced in realizing these efficiencies. In addition, health care expenditure in these countries remains extremely low compared to the developed world. Developing countries account for 84 percent of world population, contributing 93 percent of the worldwide burden of disease. However, they account for only 18 percent of global income and 11 percent of global health spending [6].

Table 1- Global comparison on per capita total expenditure on health for the period 2005-2006 (International dollars per person).

Region	Year	
	2006	2005
World	163,301	155,880
Developed Countries	115,847	111,509
Developing Countries	47,448	44,346
Monaco	7,154	5,447
United States of America	6,714	6,347
South Africa	869	811
Burundi	15	17
Rwanda	210	136
Zimbabwe	147	146

Source: Available from URL: http://earthtrends.wri.org/text/population-health/variable-1264.html

Table 1 above compares the per capita expenditure on health in international dollars per person in the years 2005 and 2006, effectively demonstrating the global expenditure disparities. In 2006, the world per capita expenditure on health in international dollars per person was 163,301. Of this amount, the developed countries spent a cumulative amount of 115,847

compared to 47,448 spent in developing countries. Focusing on sub-Saharan Africa alone, the expenditure was 7,030 of the 47, 448. Even for the most developed country in Sub-Saharan Africa, i.e. South Africa, its per capita expenditure per person was 869 compared to 6, 714 of the United States [7].

The impact of inequality in health services expenditure on individuals begins in childhood. The world average life expectancy, less than 60 years towards the end of the 1970s, now surpasses 74 years [8]. This statistic does not reflect lack of progress in developing countries, especially in the Sub-Saharan Africa region. A girl child born today can expect to live for more than 80 years in Japan, but for less than 35 years if she lives in Swaziland [9]. The factors contributing to global variation in life expectancy are quite varied. However, one key determinant is the variation in disease burden. According to WHO, the main causes of illness and death in developed countries are cancer, respiratory diseases, cardiovascular disease and conditions of the nervous system. In the developing world, communicable diseases are the main causes of the disease burden. The principal causes of death, which correlated with WHO reporting, include respiratory infections, HIV and AIDS, infections at birth, diarrhoeal disease and tropical diseases such as malaria [10].

As the leading causes of death in developing countries are communicable diseases which are treatable, there is an enormous opportunity to lessen the burden of disease. Health care service providers and policy makers acknowledge the need to prioritise scarce resources for disease prevention and curative services rather than for auxiliary services. ICT can be an effective support in the delivery of these services by significantly strengthening information systems available to clinicians and personnel, e.g. through electronic patient records and decision support services. In addition, on the basis of benefits highlighted above through ICT tools, it is essential that the health authorities of these countries allocate reasonable resources towards ICT implementation. This would also be in line with an eHealth Strategy for MS as recommended by the World Health Assembly (WHA). It is strongly suggested that health information systems should be implemented - not as a nice-to-have tools - but as part of a comprehensive eHealth strategy.

ICT in Health: Implementation Challenges

The implementation of ICT in health is a high risk process for health systems, since these initiatives are not always successful, resulting in the waste of scarce financial resources that could better have been used in saving lives. Hard lessons have been learnt when ICTs in health fail due to implementation challenges. A documented case scenario is found in the electronic health information system for the Limpopo Province in South Africa [11]. The initial objectives of this system were noble, notably to:

- Make patient information available where the patient is currently being treated.
- Improve patient administration procedures, resulting in shorter waiting times and better service.
- Improve revenue collection.

This project was one of the biggest health informatics projects in Africa, at a cost of nearly £14m, it represented 2.5% of the province's annual health and welfare budget. For various reasons the system implementation failed, clearly demonstrating the need for prudence, caution and foresight in the implementation of ICT.

Despite such failures, ICT in health in the form of Electronic Medical Record Systems and Public Health Information Systems continue to be developed and implemented in Sub-Saharan Africa - albeit at a slow pace compared to the rest of the world. The benefits of these systems to health care delivery and quality of life to populations of developing countries are undisputed and profound, to the point that failure to adopt these systems would undermine human development and well-being. A number of systems have been successfully deployed into clinical workflows [13] for patient care and disease monitoring and evaluation [14]. Though these systems have been deployed at site level, none have been demonstrated to be scaled up to wide areas of implementation between different data sources and different health information systems. There is no demonstration that these systems are capable of exchanging health information for continuity of care (for patient level data) or for the co-monitoring of infectious diseases such as HIV and AIDS, and TB. There are currently no documented cases where two or more health systems in Sub-Saharan Africa can exchange health information data. As healthcare is interplay of various service providers, each requiring different aspects of the same data, the exchange of information should surely be a critical component of healthcare delivery.

Policies Recommendations

The business of healthcare is fundamentally a collaborative process, involving different healthcare service providers utilizing different components of the same global health data. Data generation and utilization for decision makers does not follow a linear process. The diversity of health information systems requirements has largely contributed to the development of disparate non-communicating systems. Current health systems have been motivated mostly by the need to report statistics (as secondary data) for government authorities and/or funding agencies [12]. The collection, storing, revising and delivering health data has become increasingly important to demonstrate the health status of its communities, vulnerable groups and society in general. It is an unnecessary wastage of scarce resources for developing countries south of the Sahara, currently with minimal penetration of electronic health information systems, to struggle through the same hard lessons learnt in developed countries. Developing countries have a unique opportunity to demonstrate the usefulness of ICT tools in addressing their health challenges.

Though various factors contribute to the successful implementation of ICT in health [11,13,15,16,19], we believe that an enabling environment that allows for multiple health information systems exchanging data securely is fundamental to meet health service challenges particularly in achieving continuity of care across the geo-political divide while significantly optimizing resource usage in resource limited settings.

It is critical that developing countries establish harmonized frameworks or policies around health information systems management for their respective countries. This approach will ensure an effective collaboration between all the entities requiring health data. Recommendations include:

1. Security Framework: Ensure secure sharing of health data between health service providers making use of the same health data [15-17].
2. Governance of Health Data: Ensure that data elements are aligned with healthcare delivery, i.e. the numbers and description of health data elements are consistent with the current workflow of healthcare delivery services [18].
3. Adherence to Available Standards: Establish a collective approach to health information systems implementation within countries, with standards adopted and maintained at the technical, practice and policies level, e.g. utilization of an Electronic Health Standards such as Archetypes [18].
4. Interoperability or Integration Platform: Ensure semantic interoperability in the exchange of data within the health information system. This is critical for ensuring that accurate communication occurs within a collaborative health groups. Avoid duplication of virtual data within the health system [18].

Regional Recommendations for Africa

In order to achieve regional health information exchange for patient or disease monitoring across geo-political boundaries, it is recommended that regional bodies such as the Southern African Development Community, World Health Organisation Inter-Country Support Teams, the respective Ministries of Health and other stakeholders etc. collaborate in harmonising the electronic health information systems frameworks/policies as they are developed in developing countries. Currently, there is minimal inter-country collaboration with the possible risk of incompatible information systems either for patient care or regional reporting needs between countries.

It is recommended that countries and regional bloc MS build their electronic systems with the foresight of regional information exchange. In summary, this can be done through the following minimal recommendations;

- Ministries of Health, regional organisations such as SADC, WHO, UNAIDS and funders regularly consult to formulate common standards and information security protocols for regions.
- The adoption of a common information exchange format e.g. HL7.
- Common legal and ethical considerations for electronic data transmission and usage across geographic borders.
- Common patient identifier properties across regions.
- Common de-identification (anonymisation) techniques.

Through addressing only the above minimum requirements, developing countries south of the Sahara can significantly revolutionize health service provision, thus producing outstanding returns on investments.

Discussion

Current authors' knowledge and experience within the discipline of Health Informatics strongly demonstrates that it is possible to build successful electronic health information systems that are capable of scaling from one healthcare facility to regional information systems requirements by following some of the recommendations described in this paper. Sub-Saharan Africa has a unique opportunity as it has so many examples to learn from. The technological implementation of ICT in health has matured to the level of fully utilising its potential.

However, lack of collaboration and consultation between all healthcare stakeholders puts Africa at risk of the disaster of vertical data silos that cannot benefit an already impoverished population.

Conclusions

Collaboration in the development of national eHealth strategies, ranging from the work of in-country stakeholders to inter-country consultation, facilitates a cost effective enabling environment for the exchange of health information between sites, scalable to inter-country information transfer.

Acknowledgements

The first author of this paper is extremely grateful for the time of his colleagues from other countries completing this work, made possible by the collaboration between countries and engagement of cross continents work.

A Socio-Technical Approach to Continuity of Care and Electronic Records in the South African Context

Nicky Mostert-Phipps[a], Dalenca Pottas[a], Mikko Korpela[b,c]

[a] *School of Information and Communication Technology, Faculty of Engineering, the Built Environment and Information Technology, Nelson Mandela Metropolitan University, Port Elizabeth, South Africa*

[c] *Healthcare Information Systems Research and Development Unit, University of Eastern Finland, Kuopio, Finland*

Abstract

Paper-based techniques of record keeping are contributing greatly to the discontinuity of patient care among healthcare providers. To achieve continuity, access to the information contained in medical records collected by various healthcare providers is necessary. To improve the sharing of information contained in these medical records the use of electronic methods of record keeping as opposed to paper-based records becomes very important. Even though the benefits of using electronic methods of record keeping are widely documented, the majority of South African healthcare practitioners still use paper-based methods. This paper describes an explorative study to determine barriers to the adoption of electronic records in the private primary care sector of South Africa. An interpretive approach using a socio-technical systems theory perspective was used to conduct the study. Based on the analysis of the socio-technical subsystems in the South African context it was revealed that there is not sufficient information available on the barriers to adoption of electronic records and further research will be necessary to identify the barriers to the adoption of electronic records.

Keywords:

Computerized medical records systems, Medical records, Medical informatics

Introduction

Saltman, Rico, and Boerma define continuity as "the degree to which a series of discrete health care events is experienced as coherent and connected, and is consistent with the patients' medical needs and personal context" [1]. Continuity of care can further be defined based on various dimensions, including informational, longitudinal, and interpersonal continuity [2].

To achieve informational continuity it is necessary that relevant medical, social, and personal information about a patient be available to a healthcare provider at the point of care to ensure appropriate care for the patient. Longitudinal continuity refers to patient care delivered at a single point of care, involving a single medical record over a period of time, leading to growing knowledge of the patient by the healthcare provider(s) delivering the care. Longitudinal continuity should not be confused with interpersonal continuity. Longitudinal continuity simply implies a pattern of visits over time, while interpersonal, or relational continuity, refers to a particular type of longitudinal continuity. Interpersonal continuity involves an ongoing relationship based on personal trust between a patient and a healthcare provider. The patient normally trusts the healthcare provider to assume responsibility for the patients' overall health care [1-4]. According to Saultz these dimensions of continuity can be arranged in a hierarchy of increasing complexity starting with the need for informational continuity to ensure longitudinal continuity. It is also implied that longitudinal continuity is required to ensure interpersonal continuity [2, 5].

In the past the various dimensions of continuity was easily achieved since most patients received the majority of their care from the same healthcare provider from the cradle to the grave. In modern society it is highly unlikely that a patient will receive care from the same healthcare provider from cradle to grave. Even at a primary care level there is a trend towards the development of group practices where patients do not necessarily consult with the same General Practitioner every time that they visit the practice. Patients also move between different practices and healthcare providers freely. All of this makes it increasingly difficult to achieve longitudinal and interpersonal continuity of care. Informational continuity of care is thus becoming more and more important to ensure consistent, high-quality care for patients delivered by various healthcare providers [6-8]. When patients move between healthcare providers it often results in a loss of information leading to gaps or discontinuities of care [9]. To achieve informational continuity access to the information contained in medical records collected by the various healthcare providers are necessary. To improve the sharing of information contained in these various medical records the use of electronic methods of record keeping as opposed to paper-based records becomes very important [8, 10].

While various forms of Information and Communication Technologies (ICTs) are used in the South African healthcare industry to perform financial and administrative functions such as billing, the majority of South African healthcare practitioners still use paper-based methods of record keeping when it comes to patient's medical records. Paper-based

techniques of record keeping are contributing greatly to the discontinuity of care among healthcare providers and are widely considered to be inadequate in the face of an industry that is continually growing in both complexity and sophistication [11, 12]. Even though it is clear that paper-based patient medical records are becoming increasingly inadequate healthcare providers in South Africa have rarely made an effort to adopt the necessary technology, such as electronic medical records (EMRs), which will enable them to store patient medical records electronically. Many healthcare providers do not even have a computer in their consultation room. According to research by Cochrane and Ramokolo analysts estimate that only between 7% and 10% of general practitioners and specialists will be purchasing Electronic Health Records (EHRs) within the next three to five years [13].

A literature review indicated that research in the South African context is mostly focused on the implementation of hospital information systems [14] and telemedicine systems [15] in public healthcare. There is a lack of research focusing on the reasons behind South African healthcare providers' hesitance to move away from paper-based medical records.

Research Objectives

This paper describes an explorative study to determine barriers to the adoption of the necessary technology to replace paper-based patient records with EMRs in the private primary care sector of South Africa in order to improve informational continuity of care. The authors will focus on a primary care level as a starting point since primary care is the main entry point into the healthcare system for the majority of patients and it is at this level that the bulk of a patient's medical record is generated. The focus will also be on primary care in the private healthcare sector of South Africa since very little or no research in health informatics in South Africa focuses on the private care sector. Another motivating factor for focusing on the private primary care level is the South African government's plans to implement a National Health Insurance (NHI) in the future. Once the NHI is implemented more and more patients that were previously served by primary care facilities in the public care sector will now be served by primary care facilities in the private sector. This will also make EMRs even more necessary to improve informational continuity of care as patient will move back and forth between public- and private healthcare facilities.

Materials and Methods

An interpretive approach was used to conduct the study and a socio-technical systems (STS) perspective was used to investigate barriers to the adoption of EMRs in terms of the social, technological, and environmental subsystems. Since this paper forms part of the exploratory stage of a more comprehensive research project, the primary technique of a literature survey was employed as a suitable research method. A literature study of books, journals, the Internet and electronic databases was conducted to determine the barriers to the adoption of EMRs in South Africa. The findings of the literature study are subsequently described. The conclusions drawn from the observations made in this paper will contribute towards the design of further instruments to gather data (for example, surveys and structured interviews).

When significant changes are introduced in an organization that involves work redesign, it has been suggested that a socio-technical systems approach should be followed to ensure successful adoption of the changes [16, 17]. Originally developed over 30 year ago at the Tavistock Institute of Human Relations in London by Emery and Trist, with significant contributions also made by Cherns, the concept of STS was originally associated with organizational development and the re-design of work systems in offices, manufacturing environments, and the mining industry to improve the performance and effectiveness of organizations.

STS theory is based on the argument that an organization is open to influences from its environment, and that the organization is a combination of both social and technical components that must work together to accomplish tasks. The organization is thus divided into three interdependent subsystems, namely the social, technological, and environmental subsystems. The social subsystem represents the people inside the organization using technology and knowledge, the technical subsystem, to produce a product or service valued by the environmental subsystem, which includes customers, suppliers, government bodies, and other stakeholders that interact with the organization [16-19]. The concept of joint optimization also features very strongly in STS theory to ensure that the organization is designed in such a way that both the social and technical subsystems are optimized, instead of simply designing the technical subsystem without any regard for the social subsystem and then simply fitting the people to the technical subsystem afterwards. The manner in which the social and the technical subsystems interact with each other to meet the demands of the environmental subsystem plays an important role in the overall success of the organization.

Results

The introduction of an EMR (technical subsystem) will involve a significant change in the way that the healthcare provider performs his daily tasks, as well as in the tasks performed by the employees of the practice (social subsystem). Various stakeholders such as patients, medical aids and other healthcare providers will also be affected, and various policies and regulations as specified by the South African Government and Department of Health (DoH) will also have to be considered (environmental subsystem). The technical, environmental, and social subsystems in the South African context will be discussed in this section.

The technical subsystem

As previously mentioned, publicly available research focused on the South African context is mostly directed towards the implementation of hospital information systems and telemedicine systems in public healthcare. In the public sector there is literature available on a few cases of Electronic Health Records (EHRs) being installed in some hospitals [13]. An EHR is defined as [20]: *"A comprehensive, historical file of personal health information stored electronically that is*

compiled from the multiple healthcare providers treating a patient or evaluating their conditions over the course of that patient's health history." The literature is not clear on the context that the term EHR is being used in, and it could also be that they are actually referring to an Electronic Medical Record (EMR). An EMR contains patient information kept electronically by a single provider, such as a clinic, hospital, general practitioner, or other provider [21]. Pathology, radiology, or other laboratory test results can be uploaded into the EMR where the functionality is available. An EHR is a superset of various episodes of care provided by various healthcare providers [22].

Perceived technical barriers to the implementation of EHRs in South Africa include the relatively poor standard of Internet connectivity, as well as the high probability of hardware theft. For an EHR to be feasible it is imperative that all users are able to access the EHR online, but in South Africa Internet connectivity is expensive, relatively unreliable and slow [13].

The environmental subsystem

Patients form part of the environmental subsystem and during 2006 a study into the attitudes of South African patients towards using paper-based and electronic medical records was developed by Accenture and executed by AC Nielsen. The findings of the study will be discussed below [23].

The problem of discontinuity of care was highlighted by the study wherein 51% of respondents indicated that they repeatedly had to recount their medical histories when visiting different healthcare providers. Apart from the time wasted, the fact that most patients do not have the knowledge to recount their full medical histories accurately, and in sufficient detail, is a major problem. According to the study, South African patients see electronic health records as a solution to many of the problems associated with paper-based health records. In fact, 50% of respondents on medical aid are willing to pay between R20 and R100 extra per month to have their health records maintained electronically. One would assume that it would be respondents in the highest income groups that are willing to pay for electronic medical records. This is not the case. It is, in fact, the mid-income groups that are most willing to pay for this service.

Concerns relating to the use of paper-based health records range from those of privacy and confidentiality, to that of a healthcare provider not having vital medical information available at the point of care. The overall perception amongst South African patients is that electronic medical records will improve the quality of healthcare that they receive. This perception is not isolated to a single racial group, but is common to all the major racial groups in South Africa. Patients are also of the opinion that electronic records can ensure better privacy, confidentiality and integrity of health data than paper-based records.

The results of the survey demonstrate the importance of finding a solution to the problems associated with paper-based techniques of record keeping in the South African healthcare industry. With 54% of respondents being very to extremely concerned about the fact that their various healthcare providers do not have their full medical records, the problem of discontinuity of care is certainly an issue that should be addressed.

Another stakeholder that forms part of a primary care practice's environmental subsystem includes the South African DoH. According to Dr Shaheen Khotu, chief information officer for the DoH, some of the problems with the current paper-based system (in the public sector) include the time spent by healthcare personnel to locate patient records, instead of spending the time looking after patients, as well as the negative impact on the quality of care that patients receive due to a lack of vital information and misinformation [24]. There are also various initiatives in the South African public healthcare sector to replace inefficient paper-based patient records with electronic patient records. So, while there are efforts made in the public sector to improve continuity of care, the same cannot be said for the private sector.

The social subsystem

As very little publicly available information on the barriers to implementation of EMRs in the private sector in South Africa could be found, it was decided to draw a preliminary analogy from literature covering the international scene. The major concern from healthcare providers in the private sector centres around the costs involved in implementing EMRs. Perceptions are that these systems require considerable investment, without significant evidence of value, cost effectiveness, or Return On Investment (ROI) [3, 10, 11]. Adopters of these systems are not reimbursed for the cost and time spent to implement and use the systems, which also cause reservations towards adopting EMRs. There are also concerns about the usability of these systems and the impact that the use of an EMR will have on the consultation with a patient [25]. Literature on the South African perspective that the authors were able to locate echoed the international concerns. High start-up costs and concerns about the usability of these systems all indicate that it will be necessary to find an incentive to convince private practices to adopt EHRs and EMRs [13].

Discussion

Paper-based techniques of record keeping are contributing greatly to the discontinuity of care among healthcare providers and are widely considered to be inadequate in the face of an industry that is continually growing in both complexity and sophistication [11, 12].

It has been widely cited that the use of EHRs can improve the quality, safety and efficiency of healthcare delivery [21, 26]. An EHR is expected to enable continuity of care by consolidating all of a patient's health information in a single place. This will ensure that a provider has all the relevant information on which to base decisions when treating a patient. While this is the ideal, the reality is that this level of inter-provider interoperability is not likely to be achieved in the foreseeable future [27]. One of the barriers that must be overcome before the potential of an EHR can be realized is the lack of EMR implementation [27, 28].

While an EMR contains patient information kept electronically by a single provider, an EHR is a superset of

various episodes of care provided by various healthcare providers [22]. The American Society for Testing and Materials' (ASTM) Continuity of Care (CCR) and Health Level Seven's (HL7) Clinical Document Architecture (CDA) standards may be used to incorporate information representing various episodes of care contained in various EMR's in a single EHR [29].

Other components that can aid in improving continuity of care include personal health records (PHR) and electronic prescribing (e-prescribing).

A PHR is an electronic application, normally Web-based, that allows an individual to capture, access, and manage his own health information [28]. A PHR is owned and controlled by the individual and represents a repository of the individual's health information and allows the individual to have a lifelong summary of all of his health information in one convenient place. An individual can allow his healthcare provider access to his PHR, which can be a valuable source of information for improving care [27, 28].

While e-prescribing does not directly contribute to the continuity of care, it is still considered an important contributor to the vision of an EHR. E-prescribing is a valuable step towards medical practice automation, and even healthcare providers that are skeptical about implementing EMRs appreciate the benefits of e-prescribing, which can aid in recognizing the benefits of interoperability between healthcare providers. While continuity of care plays an important role in the quality of care that a patient receives, the importance of e-prescribing should not be overlooked as it reduces errors caused by handwritten prescriptions, and it is possible to build a history of all medications that have been dispensed to a particular patient. This enables the automated checking of interactions between medications and also ensures that an accurate medication list can be available at the point of care [20].

Figure 1 depicts a model of how the technological components that have been discussed above could work together to improve informational continuity of care while a national EHR is not available yet. If healthcare practitioners can be convinced of the benefits of adopting EMRs, standards such as CCR and CDA could be used to share information between healthcare practitioners to improve informational continuity of care.

While it is clear that the necessary technology and standards are available to make up the technical subsystem, further research will be necessary to determine whether private primary care practices in South Africa are aware of the benefits associated with EMRs and willing to spend the necessary funds on the hardware, software, and training necessary to make use of EMRs. In terms of the environmental subsystem there seems to be support from patients and the DoH for the use of EMRs, but the authors will use landscaping techniques to identify and investigate additional environmental stakeholders in the South African context that may have an impact on the implementation of EMRs, for example medical aids and other healthcare providers involved when patients are referred from primary care level. Very little research has been done to investigate the social subsystem. Observations made from international literature will contribute towards the design of further instruments to gather data on the social subsystem and barriers to the adoption of EMRs in South Africa.

Conclusion

Based on the explorative analysis of the social, technical, and environmental subsystems in the South African context it was revealed that there is not sufficient information available on the barriers to adoption of EMRs in private primary care in South Africa. Further research efforts will focus on gathering further data on the barriers to the adoption of EMRs in order to develop a socio-technical framework to encourage adoption of EMRs to improve informational continuity of care.

Abstract

We have adopted the Open Medical Record System (OpenMRS) framework to implement an electronic patient monitoring system for an HIV care and treatment program in Mozambique. The program provides technical assistance to the Ministry of Health supporting the scale up of integrated HIV care and support services in health facilities in rural resource limited settings. The implementation is in use for adult and pediatric programs, with ongoing roll-out to cover all supported sites. We describe early experiences in adapting the system to the program needs, addressing infrastructure challenges, creating a regional support team, training data entry staff, migrating a legacy database, deployment, and current use. We find that OpenMRS offers excellent prospects for in-country development of health information systems, even in severely resource limited settings. However, it also requires considerable organizational infrastructure investment and technical capacity building to ensure continued local support.

Computerized medical record systems, Developing countries, Mozambique, Rural health, HIV

Introduction

Mozambique, a country in sub-Saharan Africa, has a severe generalized HIV/AIDS epidemic with a national HIV prevalence rate of 16% and roughly 1.5 million persons living with HIV/AIDS, including 100,000 children [1]. The national health care system is subject to severe resource limitations, in large part a consequence of both a struggle for independence from colonial rule, and a subsequent civil war. In recent years, Mozambique has received substantial international development support, with the reconstruction of a national health system as a major focus area.

In response to the severity of the HIV epidemic, the Mozambique Ministry of Health (MOH) began an intensive ART expansion program in 2004. With support from international donor organizations, including the United States' President's Emergency Plan For AIDS Relief (PEPFAR) program, most urban centers and large hospitals now provide a range of HIV related services. Human resource capacity as well as infrastructure to support a care and treatment program for a large number of patients is much improved. However, the vast majority of Mozambicans live in rural areas, and implementing HIV care and treatment services in these areas remains very challenging.

Vanderbilt University Institute for Global Health and its affiliate non-governmental organization (NGO) Friends in Global Health, LLC (FGH) have been working in Zambézia province, Mozambique, since February 2007. The province is the largest in population size, with almost 4 million inhabitants, and second largest geographically (approx 100.000 km^2)[1]. It is a predominately rural area, with the provincial capital city as the only real urban center. The HIV prevalence is slightly higher than the national average, at 19%. The overall aim is to develop a comprehensive model for rural HIV services provision that integrates health and social services. The program currently provides technical assistance to local health authorities in 12 out of 17 districts in the province, with direct support at the principal health facility in each district. Major program elements include adult and pediatric care and treatment, prevention of mother to child transmission, and child-at risk services.

All MOH health facilities that provide HIV services use a standardized paper based patient monitoring system. It includes a facility register and a patient based paper chart, as well as a patient card that is issued on enrollment in a care program. The system suffers from redundancy due to a large number of forms and many form fields that do not correspond well with a compact data set suitable for resource constrained settings [2]. In a recent assessment, the number of data elements in the current system was found to exceed the WHO recommended set of HIV specific data elements by more than

[1] Data from the 2007 census, available online at: http://www.ine.gov.mz/censo2007/rdcenso09/zambezia/q1

a factor of two[2]. Furthermore, there is extensive use of non-coded data fields in the forms, which in general decreases the usability of data for analysis. A review and revision of the complete paper based system is included in the strategic information plan for HIV.

The rapid expansion of HIV services has already resulted in high patient enrollment numbers, and further growth is anticipated. A high patient volume inevitably results in a documenting and reporting burden on already heavily taxed human resources in the health facilities. Avoiding this scenario is a primary motivation for pursuing an electronic patient monitoring system. A growing body of evidence from case studies suggests that the use of electronic medical records in developing countries can contribute to improving the health care system [3-7]. The World Health Organization, in its recent progress report on universal access to HIV treatment, reiterated its position on the importance of strategic information, and the building of systems that improve data quality [8]. In assessing potential impact of the overall technical assistance program from FGH in Mozambique, we identified the implementation of a health information system as a key opportunity in strengthening the integrated HIV care and support program.

This paper describes our implementation of an electronic patient monitoring system for the setting described above. It includes the choice of the Open Medical Record System [9] framework, its adaptation to the local context, the actual implementation and deployment of the application, creating a local support team, information technology challenges, and current use.

Methods

Choosing the OpenMRS framework

To determine a suitable implementation path for an electronic patient monitoring system we evaluated several such systems in use both in Mozambique, and elsewhere. While we found electronic data capture relatively common, applications are typically only used internally by each organization. Within Mozambique an exception was the electronic patient monitoring system created by the *International Centers for AIDS Care and Treatment Programs* (ICAP, affiliated with Columbia University, USA). While limited in functionality or options for feature extensions, this Microsoft Access desktop database application included essential Portuguese language support, and a reasonable correspondence to the Mozambique patient monitoring system. ICAP graciously allowed FGH to use this system as an interim solution in the health facilities supported in the early phases of our program while we developed our own approach.

As the most suitable candidate for a system that will provide long term growth in supporting a range of health services, as well as facilitate eventual needs to support health services research, the Open Medical Record System (OpenMRS) emerged with the broadest set of necessary features. OpenMRS is an electronic medical record (EMR) system framework [9]. The framework is under continuous development to expand capabilities towards an increasingly comprehensive set of EMR functions [10-11]. It is also characterized by a collaborative development model, and the emergence of an "implementers' network" [12] that provides a community oriented mechanism to support new adopters, disseminate lessons learned, and establish best practices. Most deployments to date are in low or middle income countries. While larger scale or multi-facility implementations of OpenMRS typically depend on technical support from external partners, there is a strong trend towards locally sustainable development models. When an implementation incorporates a technology transfer and health information systems capacity building aspects, the implementation can increasingly be supported through local or in-country technical staff.

Electrical power and telecommunication infrastructure

The electrical power grid in Zambézia benefits from the proximity of a reliable source of electric power, a hydro-electric dam. As a result, those health facilities connected to the grid also have relatively reliable electrical power. Power infrastructure limitations still exist in three districts, but the implementation of a permanent solution for each of these sites is already in progress.

Internet connectivity at a health facility is another important objective both for general Internet access, and also to enable a health information exchange with other sites or with a regional data repository. A national telecommunications infrastructure project is underway expanding a terrestrial fiber optic network that will eventually reach all districts in the country. In Zambézia, broadband subscriber services (dedicated circuit or DSL) are gradually becoming available. We consider this to be the most promising infrastructure for long term sustainability and are adopting this service in each district where it is provided. Wireless data services based on GPRS or better are also expanding coverage area, but real world availability and data rates in rural areas remain limited. As an overall strategy we anticipate heterogeneous connectivity options for the supported health facilities.

Scope of the initial implementation

Both power and communication infrastructure concerns dictate a key macro-level architecture decision. We implement an independent EMR server at the primary district health facility, provided the facility is connected to the power grid. Access to the system is provided through a local area network and data entry terminals. This approach, while requiring more IT infrastructure is more robust than a centralized implementation. In addition, a program in multiple districts crosses administrative boundaries. Without MOH approved policies on data sharing in place we opt to keep the individual EMR repositories unconnected. Where grid power is not yet available we implement for a laptop based solution, with corresponding constraints on data availability.

While we aim to implement an electronic patient tracking system we also expect that paper based record systems will re-

[2] Patient Monitoring System Assessment, Technical report prepared by the University of California, San Francisco, for the Mozambique Ministry of Health, 2009.

main in place for the foreseeable future. Electronic systems used for retrospective data entry can provide easier access to information for the health care worker and thereby lead to improvements in providing care. True evaluation of the impact of a health information system on patient outcomes is much more challenging because the use of a health information system is rarely an isolated intervention [13]. Our direct objectives therefore are focused on improving the health care process by making clinical data available and useful.

Results

Customizing the OpenMRS framework

The OpenMRS concept dictionary, the representation of all clinical knowledge in the system, has been created to match the paper based system, and has been fully translated into Portuguese. The web based user interface has also been translated into Portuguese (although internationalization support of the web based interface remains somewhat incomplete), and localization of the patient registration section supports a structure for providing rural patient addresses.

The *de facto* application for form data entry in OpenMRS is through the use of Microsoft InfoPath. An electronic form was created to correspond to each of the paper forms with improvements in data coding and with implementation of data validation logic. OpenMRS report building functionality, available as extension modules, lacks some desired features, e.g. archiving persistent reports. However, creating an interim reporting solution has been relatively straightforward, and we expect to replace it with standard capabilities in due course.

Migration of legacy databases

The adoption of an interim database presented both an opportunity and a challenge. The databases enabled for data mining of the content, which revealed that clinicians were using their own (mostly) consistent coding schemes in some of the plain text fields on the paper forms. This provided us with an easy opportunity to improve the field values in the corresponding OpenMRS forms. The challenge came in mapping the source database model onto the OpenMRS data model to automate the data migration. A utility was created to automate the migration of all patient records from the legacy databases to OpenMRS, but the accidental complexities of the source database made creating this mapping a labor intensive process.

Deployment

Standardized Information Technology setup

For ease of maintenance and support, we select only COTS hardware in a standardized configuration. An uninterruptible power supply (UPS) can provide backup power for two hours, and a power conditioning unit protects against intermittent power quality problems. For the OpenMRS server, we employ a low-voltage and small form-factor hardware platform that has much lower power consumption than conventional server class hardware. The default configuration is a rackmount server enclosure but to accommodate very dusty conditions we can also select a fanless enclosure, at the cost of performance. High reliability data storage is realized through redundant hard drives. The server runs an open source operating system and does not require any proprietary software.
